Calculating accurate free energies of binding can be problematic, because large individual energy contributions balance to obtain a small overall binding energy, which can lead to statistical and systematic errors (Kollman, 1993; Muegge *et al*., 1995). In addition, other terms such as entropy can be difficult to determine and only approximations are available. These simplified energy functions give a fast estimation of binding affinities for determining favorable docking and *de novo* solutions, and are generally referred to as *scoring functions*. The wide variety of scoring functions implemented within docking algorithms underpins the fact that no single scoring function has been developed to correctly rank docking solutions in all cases. There has been significant focus on developing scoring functions in recent times. There have been several reviews (Gohlke and Klebe, 2001, 2002; Jansen and Martin, 2004; Tame, 1999), numerous comparative studies of scoring performance (Ferrara *et al*., 2004; Wang *et al*., 2003, 2004) and scoring function/docking algorithm combinations (Bissantz *et al*., 2000; Ha *et al*., 2000; Xing *et al*., 2004). The scoring functions of ligands ideally permit the discrimination of a solution with the correct ligand-binding mode from alternative solutions. Decoy structures are commonly used to validate the capabilities of scoring functions to detect the correct binding modes of ligands (Wang *et al*., 2003, 2004; Perola *et al*., 2004). The scoring not only needs to be able to differentiate between active and inactive compounds, but to also reduce the number of false–positives and negatives by correctly recognizing the actives. In addition to binding mode discrimination, ideally the scoring function will be capable of ranking a set of ligands according to experimental binding affinity.

A variety of scoring functions exist which can be categorized into four main groups, (1) scoring functions that are derived from first principles, (2) empirical

scoring functions, (3) knowledge-based scoring functions, and (4) other functions that use chemical scores, contact scores, or shape complementary scores.

Force field scoring functions derived from first principles have certain advantages: they are fast to compute, they are transferable and conceptually they use terms that have a physical basis. A major disadvantage of first principles force fields is that they tend to measure only potential energy with some force fields containing additional terms for solvation (ΔG_{solv}^{lig}, ΔG_{solv}^{prot}, $\Delta G_{solv}^{complex}$) and entropy ($T\Delta S$) using different theoretical models. Standard non-bonded interaction energies are calculated by most force fields with two main energy terms, the van der Waals (vdW) and the electrostatic contributions. The vdW term is generally calculated using a Lennard-Jones 6–12 potential; however, this function has been softened in some docking scoring schemes. Most often, the electrostatic term is described by Coulomb's law with scaling factors used to model the dielectic screening effects of the solvent (water). In addition, geometric-dependent, hydrogen-bonding terms may be utilized as in the case of Q-fit (Jackson, 2002) and GOLD (Jones *et al*., 1997).

Empirical scoring functions use multivariate regression methods that fit coefficients of physically motivated contributions to the binding free energy to reproduce measured binding affinities of a training set of known 3D protein–ligand complexes (Bohm, 1994; Horton and Lewis, 1992). The empirical scoring function employed by LUDI (Bohm, 1994) was further enhanced for the docking method FlexX. The free energy of binding for a protein–ligand complex is estimated in FlexX as the sum of free energy contributions from the number of rotatable bonds in the ligand, hydrogen bonds, ion–pair interactions, hydrophobic and π-stacking interactions of aromatic groups, and lipophilic interactions. The advantages of empirical scoring functions are their speed and reasonably good predictive power for binding free energies. However, conceptual disadvantages are that these functions are trained on protein–ligand complexes with medium-to-strong binding energies. Therefore due to the nature of their derivation they have no effective penalty for bad conformations and their ability to predict new structurally different complexes not in their training set, has been questioned (Ferrara *et al*., 2004).

Knowledge-based scoring is a deductive approach that uses existing protein–ligand complexes to create potentials and forces that can be used for scoring binding affinities. The idea is that forces that determine the ligands interaction with a protein are complicated; therefore, the information in protein–ligand complexes is taken as the main source of information. Deriving scoring functions for ligand–protein docking from crystal structures was inspired by the success of similar methodologies for protein folding and protein structure prediction (Sippl, 1990). Protein–ligand atom pair potentials are derived from crystallographic complexes under the assumption that the optimal placements of ligand atoms with respect to protein atoms are represented. The continual growth of structural data for protein–ligand complexes now provides several million ligand–protein atom distances. These distances can be used to create statistical preferences. One of the first investigations that incorporated knowledge-based potentials was Verkhivker et al. for the binding affinity prediction of HIV-1 protease complexes (Verkhivker *et al*., 1995). Many different knowledge-based scoring functions have

been developed in the last few years. Drugscore (Gohlke *et al*., 2000) and DFIRE (Zhang *et al*., 2005) are examples of freely available knowledge-based scoring functions for academic use.

Consensus scoring, using multiple scoring functions in conjunction with each other, have recently become a popular method of enhancing scoring function performance (Charifson *et al*., 1999; Clark *et al*., 2002; Wang and Wang, 2001; Yang *et al*., 2005). This follows from the popular concept of data fusion from Information Theory. For example, one scoring function can be used to search for the correct binding mode and another function can be used to refine the placement and correctly score the protein–ligand complex. However, increased performance with consensus scoring can only be achieved if both scoring functions differ in how they approach the scoring problem, and create a synergistic effect.

7. Virtual screening with docking

The VS of databases containing thousands or millions of compounds using docking has become a routine part of modern SBDD. VS has been shown to be a powerful method for identification of lead compounds due to its ability to rank a series of candidate ligands correctly according to binding affinity (Abagyan and Totrov, 2001; Alvarez, 2004; Shoichet *et al*., 2002). There are three main reasons why VS has become accepted and successful: (1) There is an increased amount of experimental protein structural information. (2) There is successful enrichment of compound databases with VS. (3) The speed of VS decreases the time for drug design cycles, reducing the cost of drug development.

The overall aim of a VS experiment is to reduce a database of candidate ligands to an enriched list of bioactive ligands. A variety of factors are used to evaluate and validate the quality of the methodology. For any scoring scheme, the yield is the percentage of active ligands in the top ranked compounds, and can be calculated by $(A_h/T_h) \times 100$, where A_h is the number of active compounds in a selected subset of the ranked database, and T_h, represents some predetermined number of compounds to be screened in a database of size T. The coverage of the screen, that is, the percentage of active (true positives) ligands retrieved from the database is defined as $(A_h/A) \times 100$, where A is the number of actives in the whole library database. Another factor considered is the false–positive rate given by $(T_h - A_h)/(\mathrm{T} - \mathrm{A})$. Finally the factor most widely cited by VS experiments is the enrichment factor given by $(A_h/T_h)/(A/T)$.

8. Structure-based drug design success

Over the last decade SBDD methods have improved sufficiently to be used routinely in many large-scale drug discovery projects within the pharmaceutical industry where structural information for the target is available. The recent success of SBDD in creating clinically important molecules is well documented (Hardy and Malikayil, 2003). SBDD has been utilized to create more than 50 chemical entities for clinical trials, while numerous drugs have also been approved. Specific examples

of successful drugs currently on the market are the HIV protease inhibitors Viracept (Kaldor *et al*., 1997) and Agenerase (Kim *et al*., 1995).

There are several examples where a *de novo* approach has yielded potent inhibitors. This includes, BREED (Pierce *et al*., 2004), which was used to generate a HIV protease inhibitor with nanomolar binding affinity, and TOPAS (Schneider *et al*., 2000), which was used to generate an inhibitor for a human cannabinoid receptor. A comprehensive study using a variety of *de novo* drug design tools was applied to cyclin-dependent kinase-4 (cdk4). Cdk4 plays a key role in cell division, and inhibitors could be useful anticancer agents. Honma (Honma, 2003) used LEGEND to generate around 1000 lead compounds for a homology model of cdk4. These compounds were usually not chemically synthesizable or commercially available, so the SEEDS program was used to find structurally related commercially available compounds. 382 compounds were screened against cdk4, and five compounds in the diarylurea class were found to bind with micromolar affinity. Combinatorial chemistry was used to synthesize several hundred urea compounds and one was selected (IC_{50} = 100 nM) for further optimization. X-ray crystallography revealed the binding mode of a closely related compound and a chemical library was designed to take into account the orientations of the amino acids in the binding site. LUDI and Leapfrog (2005) were used to suggest the types and sizes of the fragments for substitution. The process successfully elucidated nanomolar inhibitors.

The comparison of VS with HTS technology has provided evidence to show that these two techniques are complementary as they are capable of finding differing bioactive molecules. VS was shown to select more druglike hits than HTS for the target protein tyrosine phosphatase 1B (Doman *et al*., 2002). While another study reported the failure of HTS to identify inhibitors for DNA gyrase, an *in silico* screening and lead optimization procedure using a structure-based approach was successfully implemented to identify an inhibitor 10 times more potent than an existing DNA gyrase inhibitor novobiocin (Boehm *et al*., 2000). A large percentage of false–positives are generally found in hit lists from HTS, therefore follow-up assays are required to distinguish active from inactive substances. However, in an attempt to reduce the number of false–positives a consensus approach of using HTS in conjunction with VS was taken. The method implemented gave a sixfold enrichment over the HTS hit rate and the HTS hits ranked in the top 2% of the VS included 42% of the true hits, but only 8% of the false–positives (Jenkins *et al*., 2003).

There are a number of successful examples of structure-based inhibitor identification that cover a wide range of protein targets and identification methodologies (Alvarez, 2004). Generally inhibitors in the micromolar range are discovered; however, the potency and number of potential inhibitors reported from such screens can vary. This is dependent on methodologies, refinement of hits and the number of potential inhibitors tested experimentally. For example, a VS using pharmacophore constraints and docking on an in-house library collection for checkpoint kinase-1 identified 103 compounds for testing. From theses compounds 36 inhibitors were identified from four different classes that had a range of IC(50) value ranges from 110 nM to 68 μM (Lyne *et al*., 2004). Another study performed a VS on 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase

to reveal 44 potential inhibitors; *in vitro* inhibition assays were performed for 16 soluble compounds. Micromolar inhibition was identified for 8 compounds which contained novel scaffolds; these scaffolds were used in further docking studies to identify 11 additional compounds with one particular inhibitor having an IC(50) value of 600 nM. These 19 inhibitors served as novel scaffolds/templates for further development of potent and specific inhibitors (Li *et al*., 2004).

Homology models are traditionally less accurate than experimental models and when utilized in VS can supply inferior enrichment rates (McGovern and Shoichet, 2003). The docking tool DragHome (Schafferhans and Klebe, 2001) has been developed to try and address such issues. It combines homology model data with information about known ligands to the protein to create a pharmacophore. This idea was further developed by the same group in modeling binding sites including ligand information explicitly (MOBILE) (Evers *et al*., 2003) and has proved to be successful in VS (Evers and Klebe, 2004). There are many other examples of successful VS using homology modeling (Alvarez, 2004). Another notable and highly successful study performed by Novartis (Vangrevelinghe *et al*., 2003) used DOCK 4.0 to screen an in-house library of 400 000 molecules for inhibitors of human casein kinase II. A homology model built from the Zea mays enzyme, which has 82% sequence identity in the ATP binding site, was used. A dozen compounds were selected for testing, of which four exhibited better than 50% inhibition at a concentration of 10 mM, including an indoloquinazolinone derivative that had an IC(50) of 80 nM, making it the most potent reported inhibitor of this enzyme.

9. Summary

The number of studies involving protein–ligand docking and SBDD have grown significantly over recent years. This is probably because of the number of reported successes in the "lead" identification process using these methods. These developments have been stimulated by the wealth of experimental structural information. However, comparative modeling is increasingly playing a role. Improvements in small-molecule binding site prediction tools, advances in *de novo* drug design and docking algorithms have led to a more systematic approach to drug design.

Scoring functions play an important role in the success of SBDD, as scoring is used to identify bioactive molecules. Improvements in scoring functions and in consensus scoring schemes have increased our ability to identify bioactive molecules. All these enhancements have permitted VS to be used more routinely in the structure-based drug discovery process.

Short Specialist Review

Large complexes by X-ray methods

Poul Nissen
University of Aarhus, Aarhus, Denmark

1. Introduction

In the recent years, atomic structures of large complexes such as the 20S proteasome (Lowe *et al*., 1995; Jap *et al*., 1993), the groEL chaperone (Braig *et al*., 1994), the ribosome (Ban *et al*., 2000; Wimberly *et al*., 2000; Schluenzen *et al*., 2000; Yusupov *et al*., 2001), RNA polymerase (Cramer *et al*., 2000), and the bluetongue virus core (Grimes *et al*., 1998) have been determined by the use of X-ray crystallography. Combined with biochemical and genetic data, the characterization of these macromolecular assemblies can provide a high level of functional understanding (*see* Article 94, **What use is a protein structure?**, Volume 6). This has been very clearly demonstrated for the ribosome whose complex function in protein synthesis is now addressed at the very atomic level – a goal that would have seemed impossible to reach only few years ago. Furthermore, other methods of obtaining structural information without crystals, in particular, single-particle cryo-electron microscopy with 3D reconstruction (*see* Article 100, **Large complexes and molecular machines by electron microscopy**, Volume 6 and Article 106, **Electron microscopy as a tool for 3D structure determination in molecular structural biology**, Volume 6), can further extend the use of crystal structures in the interpretation of other functional states by docking models. Genome sequencing, microarray data, and proteome analysis by mass spectrometry (*see* Article 44, **Protein interaction databases**, Volume 5) as well as many other sources of information indicate that there is a high level of complexity in the cell depending on multicomponent assemblies and networks of interaction between macromolecules. Clearly, tomorrow's biological research will increasingly be directed towards an in-depth understanding of cell biology at the molecular level. Interesting questions are therefore: (1) how do we obtain crystals of very large assemblies so that their atomic structures can be determined, (2) how do we solve these structures, and (3) how can the methods be improved in the future?

2. Crystallization of large structures

Crystallization of large structures and complexes is no different from any ordinary protein *per se*, provided that it is available in a purified form, in sufficient amounts,

and as a stable and homogenous sample (*see* Article 104, **X-ray crystallography**, Volume 6). These criteria may, however, be difficult to meet in practice. As an example, only ribosomes from a few species and in a few functional states have so far provided well-diffracting crystals, even though ribosome samples are easily prepared with large yields from most organisms. Well-diffracting crystals of ribosome preparations represent particularly stable forms, such as the *Haloarcula marismortui* and *Deinococcus radiodurans* 50S subunit (von Bohlen *et al*., 1991; Ban *et al*., 2000; Harms *et al*., 2001). In the case of the *Thermus thermophilus* 30S subunit, a fortuitous crystal packing arrangement seems to have played a critical role in getting high resolution (Wimberly *et al*., 2000; Clemons *et al*., 2001).

The reproducibility and diffraction properties of the crystals *H. marismortui* 50S subunit were dramatically improved by a back-extraction procedure, where partitioning was obtained by precipitation in polyethylene glycol (PEG) and next solubilization at saturating conditions in the final crystallization buffer (Ban *et al*., 2000). This procedure has likely improved the homogeneity of the sample and thereby also the crystal order. The *T. thermophilus* 30S subunit was purified by an elegant procedure based on hydrophobic interaction chromatography, which enriched a subfraction of subunits without the S1 protein bound. Thereby, the reproducibility of the crystals was greatly improved. A different approach of 30S crystal improvement was based on the use of a large tungsten cluster (Schluenzen *et al*., 2000), which may have imposed a similar effect by displacing contaminating S1 due to overlapping binding sites. Crystallization of the *T. thermophilus* 70S ribosome was facilitated by a complex salt wash procedure (Cate *et al*., 1999), which has probably removed loosely bound contaminants. The *Escherichia coli* 70S ribosome, on the other hand, was stabilized by the use of polyamines (which are also natural constituents of the cytoplasm) as a critical component of the crystallization buffer (Vila-Sanjurjo *et al*., 2003). These crystals have later been optimized and now diffract to very high resolution (J. Cate, personal communication).

However, well-diffracting crystals of ribosomes in complex with, for example, the GTP/GDP binding translation factors remain to be seen. Cryo-EM studies of such complexes now routinely employ the use of single-particle classification as a prerequisite, which is to indicate that they are indeed difficult to prepare as homogenous samples (Valle *et al*., 2002; Klaholz *et al*., 2004).

Once crystals have formed, their diffraction properties may greatly improve by controlled dehydration, such as in the case of the yeast RNA polymerase II complex (Cramer *et al*., 2001; Gnatt *et al*., 1997). In general, the dehydration procedures shrink unit cell dimensions and thereby enforce intermolecular contacts. In the case of very large complexes, this may alter crystal contacts covering rather large areas and thus have a very profound effect on the crystal order. This method should always be thoroughly investigated.

The use of a double-mutant form was observed to yield the best crystals of the *E. coli* groEL complex (Braig *et al*., 1994). This strategy has also been successful for very difficult cases, such as the *E. coli* lactose permease (Abramson *et al*., 2003), which resisted crystallization for many years. The mutational strategy is particularly well suited for the crystallization of multicomponent assemblies obtained by a recombinant approach where mutant forms can readily be constructed and analyzed. In this case, the possibility of using multiple species (normally considered a good

strategy) would also be less attractive due to the laborious effort of establishing the expression system alone.

3. Data collection

Very large structures automatically lead to very large unit cell dimensions, and thus very close separation of reflections on the X-ray detector. Detectors have a finite size and, therefore, the collection of high-resolution data is challenged by the necessity to also increase the crystal-to-detector distance to separate the reflections well and to reduce the background noise. Furthermore, the reflections from crystals with large unit cells are relatively weak since fewer unit cells repeat through the crystal. The advent of third-generation synchrotrons and the recent developments of large CCD detectors with fast read-out and small point-spread on the detector surface have certainly facilitated the structure determination of large structures. However, only few beam line stations are yet able to meet all the requirements for high-resolution data collection from crystals with large unit cells. New developments in synchrotrons and beam lines will provide X-ray beams with extremely low divergence and high energy resolution, and this can be used to reduce the reflection spot size sufficiently so as to allow for more diffraction orders to be resolved per given unit of detector surface area. The development of new and larger detectors with fast read-out will be just as important.

The weak diffraction from crystals with large unit cells calls for long exposure times during collection of high-resolution data. Therefore, radiation damage will often become a serious issue, which may require the use of a few to even hundreds of crystals for a data set, even when crystals are properly flash-frozen at 100 K. An implementation of crystal mounting robotics, as scheduled for most synchrotron beam lines in the near future, will facilitate the handling and bookkeeping of many crystals and allow the user to pick only the best crystals for an optimal data collection strategy.

A particular problem arises from virus crystals that are notoriously difficult to flash-freeze for cryoprotection during data collection. Therefore, only a few or even just a single frame can be obtained from each crystal, and as many as a thousand crystals may be necessary to mount, expose, and process for a workable data set at reasonable resolution to be obtained (Grimes *et al*., 1998). This is tedious and compromises data quality. It is likely that crystals of other large assemblies in the future will suffer from similar problems, and it will be a high priority to devise protocols for the cryoprotection of such crystals.

4. Structure determination

Macromolecular crystallography provides high-throughput approaches for structure determination when phasing is based on, for example, seleno-methionine protein (*see* Article 97, **Structural genomics – expanding protein structural universe**, Volume 6 and Article 104, **X-ray crystallography**, Volume 6). However, solving very large structures means that exceptionally potent sources of isomorphous

and anomalous differences must be used to provide a signal that allows for site identification, heavy-atom refinement, and phasing. Partial seleno-methionine incorporation was obtained for RNA polymerase II, but it was insufficient for phasing (Bushnell *et al*., 2001). Likewise, it has been rationalized that seleno-methionine incorporation would be insufficient for phasing of the ribosomal subunits (Brodersen *et al*., 2003). Therefore, either heavy-atom clusters or many individual sites of strong anomalous scatterers (L-edge) are required to obtain a significant signal for site identification and phasing (reviewed by Abrahams and Ban, 2003). In particular, clusters containing either mercury (TAMM, tetrakis-acetoxymercuri methan), tantalum ($Ta_6Br_{12}{}^{2+}$), or tungsten (phosphotungstic acid derivatives) have been useful for initial phasing of very large structures, as successfully implemented for crystals of the nucleosome core (O'Halloran *et al*., 1987), the rubisco protein (Schneider, 1994), the α_2-macroglobulin (Andersen *et al*., 1995), the 20S proteasome (Knablein *et al*., 1997), the ribosome and ribosomal subunits (Ban *et al*., 1998; Clemons *et al*., 1999; Schluenzen *et al*., 2000; Cate *et al*., 1999), the bacterial RNA polymerase (Zhang *et al*., 1999), and yeast RNA polymerase II (Fu *et al*., 1999). The individual atoms of a cluster scatter in phase at low resolution (below ~6 Å) where the clusters behave as "superatoms" with hundreds to several thousand electrons. The cluster sites can therefore be located by difference Patterson maps calculated at very low resolution despite a background of tens to hundreds of thousand non-hydrogen atoms. The identification of cluster sites can also be facilitated and checked by difference Fourier maps at very low resolution if a molecular replacement solution can be obtained using a molecular envelope derived from electron microscopy as a search model. This was successfully applied for the 50S ribosomal subunit (Ban *et al*., 1998). Unfortunately, heavy-atom cluster derivatives most often turn out to be useless for phasing at higher resolution due to cluster disorder that causes the isomorphous and anomalous differences to vanish below the noise level above medium resolution (4–6 Å) where the clusters resolve into individual, yet delocalized, heavy atoms.

When low to medium resolution phases have been derived from clusters, the identification of single heavy-atom sites can conveniently be approached by difference Fourier maps (O'Halloran *et al*., 1987; Schneider, 1994), which then allow for phasing at higher resolution (<4 Å). For ribosome crystals, osmium and iridium amines were particularly helpful for phasing as single-atom derivatives (Ban *et al*., 1999; Cate *et al*., 1999; Ban *et al*., 2000; Wimberly *et al*., 2000). Osmium hexa- and pentamine as well as iridium hexamine interact gently and yet extensively with complex RNA structures, similar to the binding of hydrated Mg^{2+} ions (Cate *et al*., 1996). Further, these elements display abnormally high anomalous signal ("white lines") at the L-absorption edges and at appropriate wavelengths for data collection (1.14 and 1.21 Å for Os and Ir, respectively, at the stronger LIII edge). In hindsight, it was demonstrated for the 30S ribosomal subunit that it could be solved directly from an osmium hexamine derivative with automated site determination based on the anomalous differences (Brodersen *et al*., 2003). For the large protein structures, mercurials have been particularly useful, together with platinates – similar to ordinary proteins. Interestingly, phasing by multiwavelength anomalous dispersion (MAD; *see* Article 104, **X-ray crystallography**, Volume 6) has not

been successful for large complexes (for an exception, see Cate *et al*., 1999), probably due to radiation damage building up through data collection. Instead, single or multiple isomorphous replacements with anomalous scattering (SIRAS/MIRAS) and single-wavelength anomalous difference phasing (SAD) have been used (*see* Article 104, **X-ray crystallography**, Volume 6).

5. Density modification

With experimental phases available at high resolution, the structure determination re-enters the routines of general crystallography where density modification extends and refines the phases and produces the final, experimental map for model building. Even at medium resolution (∼5 Å), density modification proved valuable when cautiously implemented for ribosome data (Ban *et al*., 1999; Clemons *et al*., 1999; Cate *et al*., 1999). In fact, it can be shown that density modification is particularly powerful for large structures (Abrahams and Ban, 2003). In the case of the 50S ribosomal subunit, an excellent experimental map at 2.4 Å resolution was based on a solvent flipping procedure initiated using rather poor heavy-atom-derived phases extending only barely beyond 4 Å resolution (Ban *et al*., 2000).

Symmetric assemblies, such as viruses, the 20 S proteasome, and groEL, display high levels of noncrystallographic symmetry (NCS), which is helpful in the site identification of heavy-atom derivatives. More importantly, NCS allows for powerful averaging to bootstrap and refine phases. The structure determination of groEL represents a good example (Braig *et al*., 1994). A single mercury derivative was identified by the use of NCS parameterization of the heavy-atom search. The phases were refined by density modification with sevenfold NCS averaging. An initial model was constructed and then used to derive a mask of the groEL monomer. Phases were then randomized and refined by the sevenfold NCS averaging only and using the final high-resolution data set. A high level of NCS has the additional advantage that it relaxes the need for complete and accurate data collection. The structure determination of the ∼40 mio Da bluetongue virus core based on incomplete data extending to 3.5 Å resolution collected from more than a thousand individual crystals mounted at room temperature represents a stunning example (Grimes *et al*., 1998).

Short Specialist Review

Large complexes and molecular machines by electron microscopy

J. M. Plitzko and H. Engelhardt
Max-Planck-Institute of Biochemistry, Martinsried, Germany

1. Electron microscopy of native biological material

Over the past 70 years, researchers have used transmission electron microscopy (EM) to study biological objects such as cells, organelles, viruses, and isolated cellular components mostly chemically fixed and stained. However, during the last two decades, EM developed a great potential for studying the ultrastructure of native macromolecules and more recently even of living organisms at the nanometer scale. Biological material, however, is ill-suited for ultrahigh vacuum, and a constant "bombardment" of electrons creates an inhospitable environment in the electron microscope. Not until the introduction of sophisticated preparation and microscopy techniques, which are still in the state of being improved, has EM allowed in vivo studies of quasi-living organisms, native organelles, and macromolecular complexes. The commonly used preparations such as thin plastic-embedded sections or negatively stained protein complexes have been expanded and replaced by cryo-techniques, that is, the rapid freezing of biological material in the original environment or in their buffer solution on EM-grids (Adrian *et al*., 1984). Embedding samples in vitrified ice preserves the structure of interest with the demand that all the successive investigations have to be done at low temperature (~90 K) and under extremely low electron dose conditions to prevent structural changes of the specimen or smelting of the ice due to irradiation. Therefore, all low temperature methods and techniques in EM have been extended with the prefix "cryo". Nowadays, cryo-EM of isolated protein complexes and cryo-electron tomography of larger objects such as intact cells allow close-to-live investigations of biological structures at very high resolution.

2. Disclosure of the three-dimensional structure: the single-particle approach

One powerful advantage of electron microscopy is the fact that it produces projection images, unlike X-ray crystallography that yields diffraction data having

lost any information on position (phase problem). Thus, images may be treated in real space as well as in Fourier space and there is no difference whether they contain information of a single molecule without any internal symmetry or of a two-dimensional (2D) crystalline array. This given fact is exploited in the so-called single-particle approach, which enables the electron microscopist to determine three-dimensional (3D) density maps of individual macromolecules (Frank, 1996). Depending on a variety of conditions, the 3D models show near-atomic, or, in the characteristic case, intermediate resolution (≥7 Å) (Jiang *et al*., 2003; Spahn *et al*., 2001).

Projection images from macromolecules contain information on the 3D structure as 2D density profiles are characteristic of the particular orientation of the particles in the electron beam. To disentangle molecular substructures in the third dimension, a number of different images of known projection geometry have to be combined. Protein complexes not too large in size are usually oriented arbitrarily in vitrified ice, so that at least one EM image contains many different projections of the isolated protein species. Once the relative orientations of the particles are known, that is, the three Eulerian angles defining the rotation of a particle around the axes in 3D space, their projections can be virtually placed on the surface of a sphere centered to the origin of a coordinate system. The Eulerian angles exactly define the positions of the projections that can now be backprojected centrally such as to superimpose the 2D densities into a common 3D volume of the particle. The most popular and utilized reconstruction algorithm in real space is the so-called weighted backprojection (Radermacher *et al*., 1992). Very large macromolecular complexes, filamentous aggregates, or proteins embedded in biological membranes usually occur in preferred orientations in frozen samples. Here, and in cases in which nonredundant structures such as singular protein assemblies are to be investigated, the specimen is tilted around a fixed axis at a certain angular increment in the EM to obtain a series of projections. This approach of *electron tomography* is applicable almost universally if the specimen is not too thick for the electrons to penetrate.

Since the electron exposure must be restricted to a value so low so as not to destroy the sensitive biological material, the images contain a high level of so-called shot noise (statistical variation in the number of electrons detected at each pixel in the image). Additionally, electron scattering from elements low in atomic number (Z), like the constituents of most biological materials, for example, carbon, oxygen, and hydrogen produce a very weak image contrast. On the basis of these facts, biological structures are barely visible in single EM images (Figure 1a). Furthermore, the exact alignment of the particles becomes a challenge, which is tackled by averaging a large number of equivalent projections of separate molecules, thus reducing the noise level. To this end, the images of some 10^3 to 10^5 particles are sorted into distinct classes of views (Figure 1b) by multivariate statistical analysis (Van Heel and Frank, 1981). Once a large set of views is available, a preliminary 3D reconstruction can be computed and refined iteratively (Figure 1c). Typically, molecular complexes must be large in size (>200 kDa) to provide sufficient signal for the alignment at high resolution. If the particles possess a high internal symmetry, for example, virus capsids or regular structures like 2D crystals, the averaging and reconstruction process is simplified and the amount of necessary images and computation time is reduced.

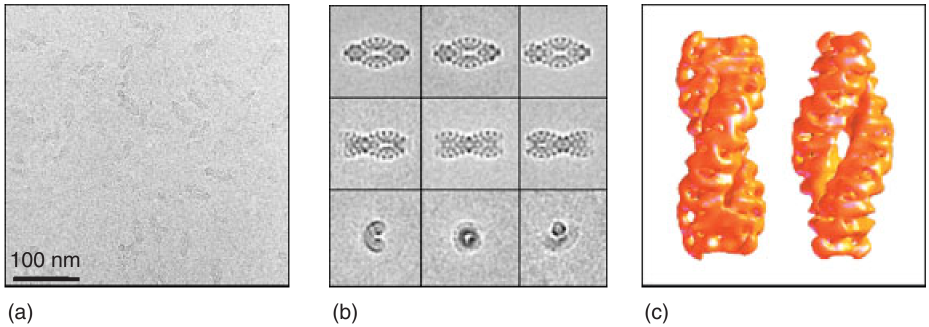

Figure 1 Single-particle investigation of the TPP II complex from *Drosophila melanogaster* embedded in vitrified ice. (a) Cryo-electron micrograph; (b) classification and averaging of a selection of different views; and (c) 3D representation of the protease TPP II complex (Reproduced from Rockel B, Peters J, Kuhlmorgen B, Glaeser RM and Baumeister W (2002) A giant protease with a twist: the TPP II complex from *Drosophila melanogaster* studied by electron microscopy. *EMBO Journal*, **22**, 5979–5984 by permission of Nature Publishing Group)

To conceive the structural basis of the working mechanism of molecular machines, we have to study the structures, positions, and interactions of their building blocks, that is, their distinct subunits. Since the structure of protein–protein contacts is only resolved at near-atomic resolution, it is hardly possible to identify molecular borders in 3D models of cryo-EM data by visual inspection. But the ability to identify elements of secondary structure, and α-helices in particular, at a resolution of about 6 to 8 Å makes it possible to fit a previously determined (atomic) model of protein subunits or subcomplexes into 3D density maps of larger assemblies obtained by cryo-EM (Li *et al*., 2002 and Bottcher *et al*., 1997). This approach, called *docking*, leads to unraveling the organization of macromolecular machines that cannot be structurally characterized otherwise. Right now researches continue to develop quantitative criteria that can guide this operation (Volkmann and Hanein, 1999).

3. The preparation problem

Single-particle cryo-EM is a powerful but still a slow method compared to X-ray crystallography, provided that for the latter, well-diffracting crystals are available. The data collection and processing can extend over several months or longer even for specialists in the field. However, with the advent of computer-controlled electron microscopes, data acquisition and analysis have become subjects for the development of elaborate automation procedures that promise to considerably reduce the time for creating high-resolution 3D density maps of large macromolecular complexes.

The real bottleneck for investigations of known or still unknown molecular machines is another experimental task. Commonly used purification procedures tend to select stable and abundant protein complexes only. Very large molecular machines, rare or transient macromolecular assemblies, complexes consisting of membrane spanning and soluble components, and all those held together by forces too weak to withstand the purification procedures, escape isolation or even

detection. The lesson is twofold: we need new approaches for isolating or reconstituting fragile assemblies, and cryo-EM of isolated single particles will probably not tell us the whole truth. To address the full complexity of functional macromolecular assemblies, noninvasive 3D imaging techniques have to take over to fulfill the task of studying the supramolecular architecture in its native, cellular context (Plitzko *et al*., 2002). The technique of *cellular cryo-electron tomography* (cryo-ET) is a “nouvelle route” with great potential in the field of structural biology that promises to provide a noninvasive and deep insight into the functional organization of the cellular proteome (Sali *et al*., 2003).

4. Cellular cryo-electron tomography

In almost the same manner as physicians obtaining tomograms from the interior of patients by means of computer tomography (CT) or magnetic resonance imaging (MRI), today’s structural biologists have begun to look inside cells using electron tomography (ET). Unlike in CT and MRI, where the patient remains still while the detector and the source rotates around him, ET applies a fixed electron beam and detector. The sample, containing native cells in frozen state (or other biological material), is tilted over a large angular range in the electron microscope. For every tilting step, an image is acquired resulting in a tilt series, which is used to reconstruct the structure of interest in 3D space. Typically, 100 to 200 images have to be recorded over an angular range of about $\pm 70^\circ$ or larger. Unfortunately, the ideal range of $\pm 90^\circ$ is not yet accessible due to the geometry of the sample and the specimen holders, with consequences for the resolution in the z-direction (Crowther *et al*., 1970).

Although it sounds straightforward to do electron tomography, and the first experiments were indeed carried out in the late 60s and early 70s of the last century (Hart, 1968; DeRosier and Klug, 1968; Hoppe, 1974), the successful application to native biological objects required substantial automation in both data acquisition and microscope control. The total exposure time for samples embedded in vitrified ice is limited to approximately 5 min for an entire tilt series at low-electron-dose conditions. Within this time frame, up to hundreds of images with a sufficient signal-to-noise ratio have to be recorded. This is only possible by automated computer control concerning corrections such as lateral shift of the region of interest and changes in focus upon every tilting step, with the aim of minimizing the necessary irradiation. In this way, only a few percent of the total electrons are used for the adjustments (Dierksen *et al*., 1995), a value that could never be achieved by manual operation. Nevertheless, the automated acquisition of a whole tilt series, for example, with an angular increment of 1.5°, requires 3 to 4 hr even today.

With automated cryo-electron tomography, it is possible to obtain molecular-resolution tomograms of structures as large and complex as whole prokaryotic or thin eukaryotic cells (Koster *et al*., 1997; Medalia *et al*., 2002; Gruenewald *et al*., 2003). Such tomograms are essentially 3D images of the cell’s entire proteome. They reveal information about the spatial relationship of macromolecules in the cytoplasm and provide us with the possibility of identifying large protein assemblies and molecular machines in their functional environment (Figure 2).

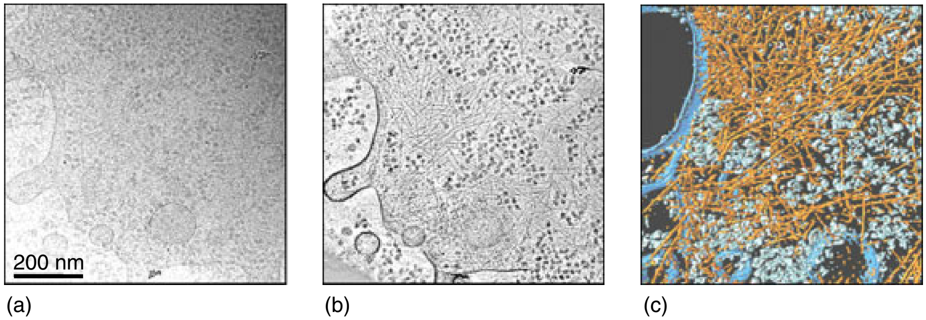

Figure 2 Electron tomographic investigation of the slime mold *Dictyostelium discoideum* embedded in vitrified ice. (a) Cryo-electron micrograph at 0°; tilt (conventional 2D projection); (b) tomographic reconstruction from a complete tilt series (120 images); and (c) visualization by segmentation. Large macromolecular complexes, for example, ribosomes are shown in green color, the actin filament network in orange-red and the cells' membrane in blue (Reprinted from Medalia O, Weber I, Frangakis AS, Gerisch G and Baumeister W (2002) Macromolecular architecture in eukaryotic cells visualized by cryo-electron tomography. *Science*, **298**, 1209–1213, **http://www.sciencemag.org** by permission of American Association for the advancement of Science)

However, the corresponding exploitation of tomograms is still hampered by two major technical problems, the inherent residual noise present in any cryo-EM data and the missing information resulting from the incomplete tilt range. Current efforts in electron microscopical image processing and technical development is focused on improving these situations. Moreover, the cytoplasm is very densely packed, with macromolecules literally touching each other, a phenomenon known as *macromolecular crowding* (Ellis, 2001). Feature extraction (*segmentation*) by visual inspection is therefore limited to large and easily recognizable structures, such as membranes or the cytoskeleton (Figure 2c).

The identification of specific molecules highly depends on the size of the complexes in question and on the resolution of the tomogram (which in turn depends on a number of technical features from the electron source to the camera recording the signal). Computer-based pattern recognition techniques have to be used for a systematic search of the reconstructed volume (Boehm *et al*., 2000; Frangakis *et al*., 2002). The prerequisite of such a molecular signature–based approach is a high-resolution structure of the template molecules obtained by X-ray crystallography or cryo-EM (Sali *et al*., 2003). It is obvious that the quest for molecules inside cellular tomograms is computationally demanding, suggesting parallel processing, since molecular complexes occur in any possible position (x, y, z) and orientation (Eulerian angles: θ, φ, ψ). Ideally, this search will be exhaustive, detecting all copies of the target molecules and their possible interactions inside the cell. In the future, the perfection of such pattern recognition tools will be crucial for taking full advantage of the power of cryo-ET.

With the current (nonisotropic) resolution of 4 to 6 nm, one can address larger complexes (>400 kDa) within a cellular context. However, there is still potential to widen the scope of cellular tomography. Ongoing instrumental developments, such as liquid helium cooling, improved detector designs and dual-axis tilting, reducing the missing angular information, make a resolution near 2 nm a realistic goal for the future.

Short Specialist Review

The importance of protein structural dynamics and the contribution of NMR spectroscopy

Arnout P. Kalverda, Gary S. Thompson and W. Bruce Turnbull
University of Leeds, Leeds, UK

1. Introduction

Over the last 25 years, the traditional crystallographic picture of biomolecules as static entities has been superseded by the realization that proteins are conformationally flexible and display dynamic motions on a variety of timescales (*see* Article 95, **History and future of X-ray structure determination**, Volume 6 and Article 104, **X-ray crystallography**, Volume 6). Solution state Nuclear Magnetic Resonance (NMR) spectroscopy (*see* Article 105, **NMR**, Volume 6) experiments play a major role in revealing the conformational dynamics that are essential to many biochemical processes, including protein folding, molecular recognition, enzymatic catalysis, allosteric interactions, and interdomain motions. In such studies, the greatest strength of NMR lies in being able to monitor simultaneous processes that may occur on picosecond to millisecond timescales (Figure 1), and at multiple atom-specific sites within a biomolecule, without recourse to site-specific labeling. Although the technique is limited to systems of tractable mass (currently <100 kDa), requires biomolecules enriched in certain stable isotopes (typically ^{2}H, ^{13}C, and ^{15}N), and employs specialized equipment and experiments, the rich insights that can be derived from NMR experiments more than justify investment in the technique.

2. NMR methods for measuring protein dynamics

The NMR methods used for measuring dynamics in biomolecules can be classified into four main categories in order of current importance: relaxation, chemical exchange effects, hydrogen exchange measurements, and averaging of dipolar couplings.

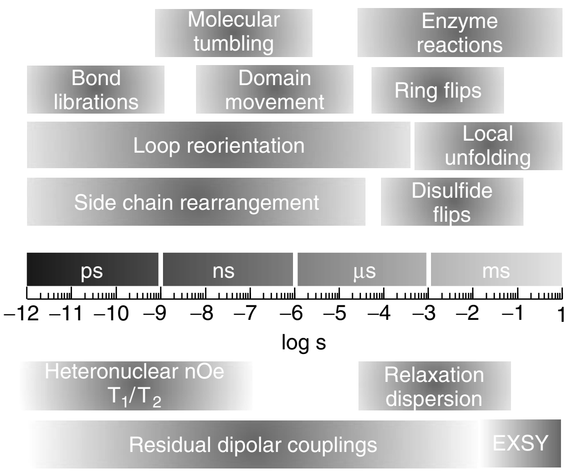

Figure 1 Timescales for different dynamic processes exhibited by proteins, and NMR methods applicable for studying these processes. EXSY: exchange spectroscopy

In NMR, unlike most forms of spectroscopy, excited states require stimulation to return (relax) to equilibrium (*see* Article 105, **NMR**, Volume 6). Ultimately, this stimulation is provided through the Brownian motion of the molecules. The frequency spectrum of motions arising from overall molecular tumbling, and also faster internal motions, thus determines the relaxation rate. Longitudinal (T_1) and transverse (T_2) relaxation and nuclear Overhauser effect measurements can provide information on molecular motions occurring on nanosecond–picosecond timescales (Palmer, 2001). Together, these parameters can be used to calculate conformational entropies for individual residues (Palmer, 2001).

Where two or more different conformations of a protein interconvert on a microsecond–millisecond timescale, chemical exchange effects may arise in the NMR spectra. In such instances, methods such as relaxation dispersion experiments can be used to determine the exchange rate for these processes (Loria *et al*., 1999).

Hydrogen atom exchange between a protonated protein and a deuterated solvent can be used to monitor the breaking and forming of hydrogen bonds associated with dynamics on timescales of seconds to months, for example, protein breathing motions or unfolding (Krishna *et al*., 2004).

Residual dipolar couplings (RDCs) provide a new method that may allow dynamics to be measured over a wide variety of timescales (Lukin *et al*., 2003), including microsecond–millisecond. RDCs arise when molecules become partially aligned with the magnetic field, a phenomenon that may occur in the presence of a molecular barrier, such as a liquid crystal. The magnitudes of RDCs are reduced in dynamic systems, as internal molecular motions average away the effects of the molecular alignment (Griesinger *et al*., 2004). RDCs have been employed successfully for defining the extent of domain motions in multidomain proteins. Together, these different methods allow the study of molecular motions that occur over a very wide range of timescales, including those that are critical to a protein's function.

3. Enzyme active site dynamics

Often, changes in protein conformation and/or dynamics occur in response to ligand, or substrate, binding. Thus, conformational dynamics must play an integral role in enzymatic processes. The binding site must be accessible for its substrate to dock, yet the catalytic reaction may have to be shielded from solvent, and finally, the enzyme must be able to release the reaction products to allow catalytic turnover. NMR relaxation measurements often reveal the presence of microsecond–millisecond dynamics in enzyme active sites. In some cases, it can been shown that these dynamics are correlated with the processes involved and it is even possible to monitor them during catalytic turnover (Eisenmesser *et al*., 2002).

The ubiquitous enzyme dihydrofolate reductase (DHFR, EC 1.5.1.3) has been studied extensively by NMR and crystallography (Schnell *et al*., 2004). NMR studies of DHFR:folate complexes show that the Met20 loop, which protects the active site during catalysis, is in exchange between two states (occluded and closed) that were observed previously in X-ray structures. On forming the full DHFR:Folate:$NADP^+$ product complex, the Met20 loop closes around the nicotinamide ring of $NADP^+$ in its binding pocket (Figure 2). This change in conformation, from occluded to closed forms, is mirrored by a reduction in the amplitude of picosecond–nanosecond motion of backbone atoms in the Met20 loop. NMR dynamics measurements of this system have also indicated that the dynamics of the Met20 loop control product release and turnover. Active site motions, which occur on the same timescale as the key catalytic hydride transfer step, have also been detected by NMR methods.

The conformation of catalytic residues that stabilize a transition state may be of higher energy than the ground state conformation of the protein. Dynamic motions of catalytically important residues can thus control catalysis by repositioning side chains in their most productive conformations. Furthermore, dynamic fluctuations in the active site can potentially be harnessed to drive the reaction, and more distal

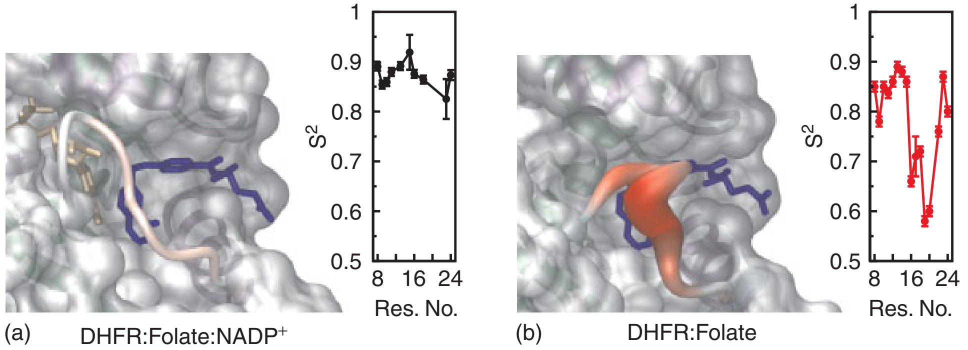

Figure 2 Structure and dynamics of the DHFR binding site showing the Met20 loop in (a) the closed [1RX2], and (b) the occluded conformations [1RX7]. The low-order parameters (S^2) shown for the occluded conformer demonstrate that the loop is very flexible (Schnell *et al*., 2004). The degree of flexibility is indicated on the protein structure by the width of the sausage representation of the Met20 loop and also by its color (white to red = ordered to disordered). Folate and $NADP^+$ are depicted in blue and gold, respectively

changes in dynamics can help reduce the entropic cost of forming the catalytic state (see next section).

4. Entropy, allostery, and preexisting equilibria

Comparative studies of a receptor in the presence and absence of ligand allow measurement of changes in dynamics that occur during complex formation. Amino acid residues forming a binding site are often rigidified upon association with a ligand. Although this process makes an unfavorable entropic contribution to the free energy change, its effect is often reduced by more distant residues becoming more mobile (Stone, 2001). In cases where proteins have multiple binding sites, differential dynamics on ligand binding can also contribute to allosteric effects. For example, when one Ca^{2+} ion binds to calbindin D9k, the remaining, unoccupied binding site becomes more rigid. The entropic cost of binding a Ca^{2+} ion to the second site is thus lowered, and hence positive cooperativity or 'dynamic allostery' results (Maler *et al*., 2000). Conversely, for cytidyltransferase, both binding sites retain some flexibility on binding the first ligand but decrease their dynamics on binding to a second ligand molecule, with a concomitant negative cooperativity (Stevens *et al*., 2001).

Protein activation pursuant to phosphorylation, or interactions with a ligand or another protein, is widely believed to result from changes in conformation. However, as proteins exist in solution as a dynamic ensemble of conformational substates, the active conformer may already be present, albeit in low concentration. NMR studies demonstrating the presence of millisecond timescale dynamics or domain orientations that differ from those in crystal structures can provide evidence for the existence of multiple interconverting conformations. For example, NMR studies have revealed that hemoglobin, the archetypal allosteric system, has an interdomain orientation, in solution, that is midway between the two allosterically distinct states (Lukin *et al*., 2003). A shift in equilibrium between the preexisting, different conformational states upon oxygen binding could be involved in the allosteric effect.

Protein conformational dynamics influence the thermodynamics of essentially all biomolecular interactions. Understanding these dynamic processes is essential if we are to succeed in rational drug design, and NMR spectroscopy continues to be the most powerful technique available to achieve this goal.

Short Specialist Review

New approaches to bridging the timescale gap in the computer simulation of biomolecular processes

Leo S. D. Caves
University of York, York, UK

Chandra S. Verma
Bioinformatics Institute, Singapore

1. Introduction

A recent study of water permeation across a biological membrane (de Groot and Grubmüller, 2001) is something of a landmark in the field of atomistic computer simulations in molecular (structural) biology (Karplus and McCammon, 2002). Although significant work has been going on in the field for decades (Duan and Kollman, 1998; McCammon *et al*., 1977), this study represents the first time that a significant biological event was observed in "real time" in a computer simulation. While there are several examples of the successful use of simulations to provide insight into the mechanisms underlying fundamental biomolecular processes (Karplus and Gao, 2004; Garcia-Viloca *et al*., 2004; Marszalek *et al*., 1999), investigations of events occurring on a biologically relevant timescale are still in their infancy (Snow *et al*., 2002). The main bottleneck in the application of molecular dynamics (MD) simulations is the timescales that can be simulated, which are typically orders of magnitude smaller than those characteristic of the processes of interest to most biochemists and biologists.

2. Addressing the timescale problem: new approaches in biomolecular simulation

The agreement of MD simulations with experimental data (where available) for processes on short timescales is heartening (de Groot and Grubmüller 2001; Snow *et al*., 2002; Meller and Elber 1998). However, there is a need for alternative methods, complementary to MD, that extend the reach of simulation and that widen the scope of applications to encompass biomolecular processes on timescales that begin to approach physiological relevance (Elber *et al*., 2003).

One class of methods, that fully exploits the fruits of structural biology, makes use of multiple structures (such as the *reactant*, *product*, and/or intermediate states) that are representative of a biomolecular process of interest. These methods address the pathway of conformational changes within (and between) the biomolecule(s) associated with the process. One approach (e.g., Fischer and Karplus, 1992) addresses the problem of the pathway from the perspective of the classical (adiabatic) reaction coordinate, and focuses on features of its underlying potential energy surface. Such approaches are essentially static, and dynamic information must be inferred by the application of appropriate rate theories. By contrast, a second class of methods attempt to address the timescale of the process by explicit consideration of the dynamics associated with the pathway (Elber *et al*., 2003; Straub *et al*., 2002; Bolhuis *et al*., 2002).

The former approaches can generate a pathway that is representative of a process at (absolute) zero temperature and focus on locating stationary points and other features of the potential energy along the reaction coordinate. However, while they yield accurate enthalpic barriers, they do sacrifice the recovery of entropic information and thus any direct considerations of the free energy of the process. The free-energy profile (the *potential of mean force*) is typically recovered by subsequent conformational sampling about the adiabatic reaction coordinate by constraint or restraint methods (Roux, 1995).

The latter class of methods recognizes and embraces the fact that, in general, biological processes operate in a fairly limited range of finite temperatures. The consequence of an explicit consideration of temperature in a process is that a single reaction pathway picture is not appropriate and processes are best characterized by a distribution (or ensemble) of pathways, which are typically considered (and optimized) as a whole (in contrast to a focus on individual critical points). Timescales in such methods are typically recovered by the appropriate consideration of energetic properties (such as the classical action) of the whole pathways associated with the process (Elber *et al*., 2003).

3. Success stories in the simulation of biomolecular processes

A specific algorithm (of the first class mentioned above), the conjugate peak refinement (CPR) method, which determines the saddle points associated with the process of conformational change between two given states of a biomolecule, has been implemented in the TRAVEL module of the CHARMM simulation software (Fischer and Karplus, 1992). We and others have applied CPR to the generation of pathways of biomolecular conformational processes in systems as diverse as ice and proteins, and have found very good agreement with experimental activation enthalpies (Verma *et al*., 1996; Fischer *et al*., 1998; Bondar *et al*., 2004). In one particular case (Fischer *et al*., 1998), the method was extended to estimate the activation entropy. In this application, it was fortuitous that the processes exhibited a relatively "smooth" energy profile. In general, a biomolecular pathway is likely to be characterized by a "rugged" energy profile, which makes robust estimates of thermodynamic parameters (via methods such as importance sampling) substantially more difficult.

4. Simulations in the era of large-scale computing: sampling and sophistication

The rugged character of the energy landscape of biomolecules (Frauenfelder *et al*., 2003), which confers their rich and complex dynamical behavior, poses a sampling problem in biomolecular simulation (Clarage *et al*., 1995). There has been a long-standing debate (without consensus) in the field of MD simulations as to whether it is best to generate one long trajectory or several short ones (Caves *et al*., 1998; Auffinger *et al*., 1995). The advent of high-performance clustered and distributed computing, and thus the unprecedented opportunity to perform very long simulations (e.g., Snow *et al*., 2002), offers a way forward in this regard.

Already, initial concern over whether the current force fields, which have traditionally been parameterized and tested over short timescales, would behave well at longer timescales seems to be dying. Other uses of the larger capacity for simulation resulting from ever-increasing computing power are in improvements to the representation of the underlying system interactions and environmental conditions such as pH (Janin and Simonson, 2004). However, the traditional tension endures: the cost of the increased physical fidelity obtained by greater sophistication of the model representation must be traded against the cost of effective and representative sampling (the extent and duration of the simulations).

5. Looking to the future: exploiting the convergence of timescales simulation and experimental studies of protein dynamics

Commensurate with the increasing reach of simulation methods into longer time-scale processes, is the increasing resolution of time-resolved (single molecule) spectroscopies (Michalet *et al*., 2003). In this context, we have embarked on a program of research to learn how best to exploit this convergence of simulation and experimental timescales (Figure 1). Initially, we are working from the perspective of a protein as a complex many-body dynamical system. As such, we take inspiration in our approach from the concepts of dynamical systems theory and in particular the embedding theorem (Takens, 1981; Packard *et al*., 1980). Briefly, the embedding theorem states that a scalar time series of a dynamical system contains sufficient information to allow for the reconstruction of its (multidimensional) phase space (Sauer *et al*., 1991).

Thus, if we have a scalar signal from a protein, such as the distance between the lobes of a two-domain protein – the kind of information that is amenable to extraction using current state-of-the-art single molecule spectroscopy – then from the methods of *embedology* (Sauer *et al*., 1991), this signal should contain sufficient information to characterize the inherent dynamics of the whole protein. This could, in principle, lead to knowledge of the system phase space geometry and topology, which are fundamental to the characterization and understanding of a dynamical system.

This is suggestive of a potentially rich means for comparing the view of protein dynamics derived from experimental methods, with that emerging from the ever-increasing reach of molecular dynamics simulation(s). In a model study of the protein

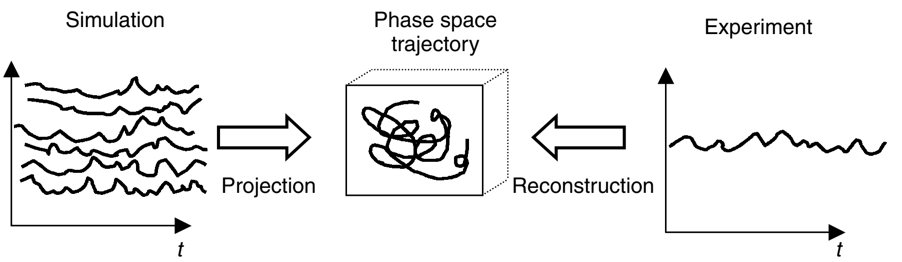

Figure 1 A schematic representation of the potential exploitation of the simulated and experimental data on biomolecular dynamics from a dynamical systems perspective. The left panel represents the multidimensional time series of properties (such as atomic coordinates) characteristic of trajectories generated from MD simulations. A low-dimensional view of the phase (conformational) space sampled in such trajectories is often generated by multivariate projection methods, such as principal component analysis (PCA). The right panel represents a time series of a scalar property of a biomolecule, such as that available from time-resolved spectroscopies. The high(er) dimensional phase space of the biomolecular system may be reconstructed by embedding the time series in a high(er) dimensional space. As the timescale gap closes, a consideration of the phase space behavior in both approaches has the potential for a more intimate comparison of the experimental and simulated data on protein dynamics leading to greater insight into the rich phenomena of biomolecular dynamics

crambin (Caves and Verma, 2002) using simulated data, we have provided an empirical demonstration of the embedding theorem in the context of biomolecular dynamics. We now look forward to applications contrasting experimental and simulated data on the same system.

Short Specialist Review

Modeling membrane protein structures

Yalini Arinaminpathy and Mark S.P. Sansom
University of Oxford, Oxford, UK

Integral membrane proteins (*see* Article 15, **Handling membrane proteins**, Volume 5) constitute ~25% of all genes (Wallin and von Heijne, 1998) and play key functional roles in cells, for example, as receptors, ion channels, and transporters. Hence, they dominate lists of predicted drug targets (Terstappen and Reggiani, 2001). Despite their importance, comparatively little is known of the structure of membrane proteins. Of the ~24 000 structures in the current PDB, only ~50 are membrane proteins. This disparity is largely due to the experimental difficulties in overexpression of integral membrane proteins and in growth of crystals suitable for structural determination by X-ray diffraction. Alternatives to X-ray diffraction have been used to determine membrane protein structures, including NMR from detergent/protein micelles and electron microscopy from two-dimensional membrane crystals. However, the resolution of the resultant structures does not match that of X-ray diffraction. A further limitation is that overexpression of *mammalian* membrane proteins remains a challenge. Thus, the majority of the structures of, for example, ion channels and transporters are for bacterial homologs. For all of these reasons, there is an almost overwhelming need to generate accurate structural models of membrane proteins, especially to aid in dissection of structural/functional relationships by mutagenesis and related methods. Models of membrane proteins can also be used to study their conformational dynamics. Both modeling *per se* and simulations of membrane protein dynamics have been made feasible by recent advances in computing power and software.

Modeling the structures of membrane proteins is somewhat simpler than that for soluble proteins as the constraints introduced by the membrane restrict the number of possible architectures. Indeed, other than the bacterial outer membrane proteins (Wimley, 2003), the vast majority of membrane proteins are composed of bundles of transmembrane (TM) α-helices. Membrane protein modeling can be broken down into three levels: prediction from sequence of the location of TM helices; homology modeling of membrane protein folds; and model evaluation and refinement.

Prior to attempting to model the three-dimensional structure of a membrane protein, it is important to identify the TM domain(s) within the larger membrane protein and to identify the location of the membrane-spanning α-helices. A number of TM helix and topology prediction methods are available. A recent study (Cuthbertson, Sansom & Doyle, ms. in preparation) suggests that most accurate

methods include TMHMM2 (Krogh *et al*., 2001), MEMSAT2 (Jones, 1998), and SPLIT4 (Juretic *et al*., 2002) and that a consensus method may be a little more accurate. However, although these methods exceed 80% accuracy in their overall per residue accuracy of TM helix prediction, they are still inevitably approximate in predicting the exact start and end positions of TM helices.

If there is detectable sequence similarity between two proteins, structural similarity can be assumed. If the three-dimensional structure of a (usually bacterial) homolog of a membrane protein of interest is known, then one may use homology modeling. Homology modeling is composed of four sequential stages. The first and most crucial step is template selection. The structural similarity between the template and target declines as the sequence identity between the two proteins decreases. If there is less than ∼25% identity between two sequences, identifying a suitable template may be problematic, although prior biological knowledge and the use of more sensitive sequence similarity search methods (e.g., PSI-BLAST) may help. Once a template has been found, the sequences must be optimally aligned. Alignment quality has a major impact on the accuracy of the resultant three-dimensional models. An optimal alignment is more difficult to achieve as the sequence identity falls, with alignment errors becoming common in the "twilight zone" of less than ∼30% identity. Multiple sequence comparisons and experimental data, for example, from mutagenesis studies may be used in optimizing an alignment.

Once an alignment has been constructed, a three-dimensional model of the protein may be built using the template structure to determine the fold of the model. This can be done using a number of homology modeling programs, for example, MODELLER (Sali and Blundell, 1993) (**http://salilab.org/modeller/modeller.html**). In general, spatial restraints are mainly determined from the alignment of the target sequence to the template protein structure, but may also be derived from, for example, NMR, cross-linking, or site-directed mutagenesis data. Models are generated by minimizing the violations of all the specified restraints. Loop regions may be modeled by searching a database of known loops. Spatial restraints are combined with potential energy terms (e.g., from the CHARMM force field) in order to enforce correct (local) stereochemistry. Together, the restraints and energy terms yield an objective function. A model is generated by optimizing this function in Cartesian space.

It is important to try to assess the quality of a model before further interpreting it. If errors are found in the model, it may be necessary to revisit earlier steps in the modeling process. For example, one may wish to adjust the initial alignment or perhaps even search for an alternative template (if available). Stereochemical tests of model quality within, for example, MODELLER may be supplemented by more general "protein-checking" programs such as PROCHECK (Laskowski *et al*., 1993). In addition to these general programs, we may examine key features of the model in the context of our increased understanding of aspects of membrane protein architecture (Ulmschneider and Sansom, 2001). With an increasing number of structures being determined, it is becoming possible to use structural bioinformatics tools to identify general features of membrane proteins. For example, statistical analyses of known structures have revealed a preference for glycine residues at the interfaces between tightly packed TM helices (Javadpour *et al*., 1999). Also, proline

residues occur with a high frequency within TM helices, where they may function as a molecular hinge (Cordes *et al*., 2002). Also important are "belts" of amphipathic aromatic residues (i.e., Trp, Tyr) at the membrane/water interface (Killian and von Heijne, 2000) and (especially in bacterial membrane proteins) a preponderance of basic residues (Lys, Arg) immediately adjacent to the intracellular ends of TM α-helices (von Heijne, 1992). Such rules derived from an increasing dataset of structures can be used to help evaluate the plausibility of membrane protein models.

After a membrane protein model has been generated, it may be further evaluated and explored by performing molecular dynamics simulations (Domene *et al*., 2003) of the model protein embedded in a lipid bilayer. Such simulations enable one to explore the conformational dynamics of the protein in relation to its biological function. The degree of conformational drift in such simulations may also aid in the evaluation of the stability of a model.

Modeling studies have been used to study a number of membrane proteins, including members of the aquaporin (de Groot *et al*., 2001) and potassium channel (Capener *et al*., 2000) families. As an example of such studies, we will take the case of the TM domain of the bacterial glutamate receptor, GluR0, which being a combination of sequence comparison and functional studies (Chen *et al*., 1999) has demonstrated to be homologous with a bacterial K channel, KcsA (Zhou *et al*., 2001). GluR0 (which forms a potassium-selective glutamate-activated channel) has a 31% sequence identity to KcsA within the core TM domain formed by the α-helical M1, P, and M2 regions. An alignment was generated for the core M1, P, and M2 regions, taking notice of the fingerprint TVGYG motif associated with K^+ selectivity, which is present in both KcsA and GluR0. MODELLER was employed to construct an ensemble of 25 models of the tetrameric TM domain GluR0, using secondary structure restraints to ensure that the M1, P-helix, and M2 regions were α-helical. The 25 models were ranked by analysis of their stereochemistry and deviation from the template, KcsA. The highest-ranking structure was selected for further analysis and as a starting structure for molecular dynamics (*see* Article 102, **New approaches to bridging the timescale gap in the computer simulation of biomolecular processes**, Volume 6) simulations (Arinaminpathy *et al*., 2003).

The similarity of surface side chains in the KcsA crystal structure and the model of the TM domain of GluR0 support the plausibility of the model (see Figure 1). For example, both the crystal structure and the model have bands of amphipathic aromatic side chains (i.e., Trp, Tyr) at the presumed location of the lipid headgroup/water interface. Furthermore, both the crystal structure and the model have rings of acidic side chains at the mouth of the pore, a feature associated with potassium channels. MD simulations based on the GluR0 model confirm that it forms a relatively stable TM domain and that it will allow permeation of K^+ ions through the membrane. Thus, the model may be used to aid interpretation of aspects of GluR0 function.

In summary, as our database of membrane protein structures expands, molecular modeling will play an increasingly important role in enabling extrapolation from known structures of bacterial membrane proteins to generate models of their human homologs. As the pace of membrane protein structure grows, it will be important to develop high throughput approaches for modeling and simulation of membrane proteins.

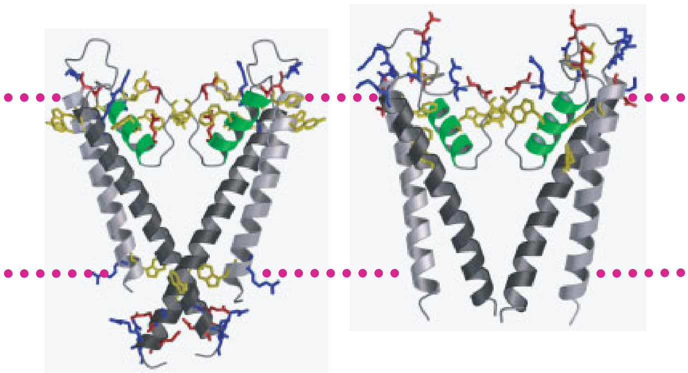

Figure 1 The structure of an integral membrane protein (the TM domain of a bacterial potassium channel, KcsA) is compared with a homology model (the TM domain of a bacterial glutamate receptor, GluR0). In each case only two of the four subunits are shown, for clarity. Basic (blue), acidic (red) and amphipathic aromatic (yellow) side chains are shown. The dotted horizontal lines indicate the approximate location of the lipid head groups of the membrane in which the proteins are embedded

X-ray crystallography

Susan Firbank
Wadsworth Centre, New York State Department of Health, Albany, NY, USA

1. Introduction

Before the reporting of the first protein crystal structure, that of myoglobin, in the late 1950s (Kendrew *et al*., 1958), little was known or even imagined about the form of proteins. Since then, approximately 20 000 X-ray structures have been deposited in the Protein Data Bank (PDB) (**http://www.rcsb.org/pdb**). They have revealed how proteins are folded and how they carry out their functions: enzymes have been trapped with substrates bound at the active site, illustrating the reactive mechanisms; receptors are found with their ligands bound revealing the conformational changes induced upon binding; and protein complexes have been observed in their functional arrangements. Traditionally, structures determined have been of proteins for which the functions are known. Today, however, structural-genomics projects are providing new scope and opportunity for the crystallographic community to assist in the characterization of a long list of, so-called, hypothetical proteins – proteins for which only the sequence is known. It is hoped that where sequence analysis fails, the structure will allow functions to be assigned to the uncharacterized proteins. Nevertheless, regardless of the purpose of a particular structure determination, the methods that must be applied are the same.

2. The crystallographic method

Structure determination by X-ray crystallography can at first be considered analogous to the examination of objects under the light microscope. As the light passes through the sample, it is diffracted and then refocused with lenses to allow visualization of the sample object. A similar process can be carried out to examine proteins, although electromagnetic radiation in the visible range cannot be used since the required information is on a scale much smaller than the wavelength of visible light. X rays with wavelengths in the low nanometer range are used for structural analysis of proteins, since they are of the same order of magnitude as the atom separation within proteins: ~ 0.1 nm, or 1 angstrom (Å). While conceptually similar, the process required to obtain the structure of a protein by X-ray diffraction is in practice more complicated than the visualization of objects using the light microscope.

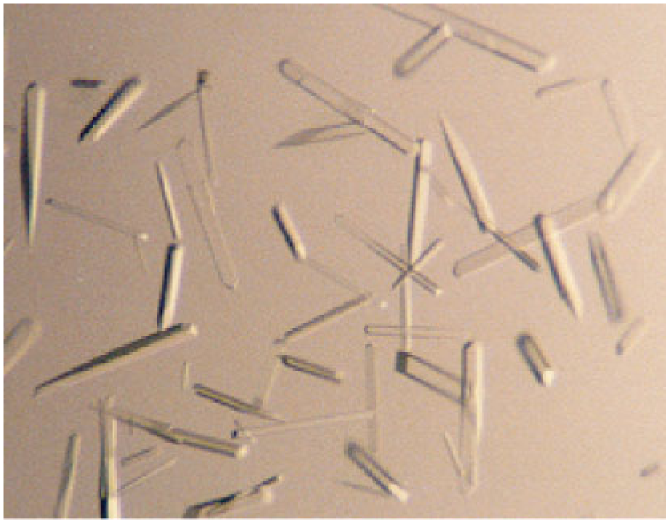

Figure 1 Examples of protein crystals. The longest dimension of these crystals is <0.5 mm. Individual crystals can be used in diffraction experiments. Data can be collected either at room temperature, but are often also collected at 100 K to reduce damage to the crystals by the X-ray radiation

The first hurdle to be overcome is that the scattering of X rays from a single protein molecule is not great enough to allow detection, and so, in order to increase the intensity of the diffraction obtained, the protein is crystallized (Figure 1) to generate repeating units of protein molecules, thus amplifying the signal. The scattered waves add up when they are in phase owing to constructive interference whilst waves that are out of phase cancel each other out owing to destructive interference (Figure 2). Detection of the resulting waves reveals an array of spots with measurable intensities (Figure 3) where the spacing of the spots is dependent upon the size of the repeating unit within the crystal and the intensities are a consequence of the arrangement of electrons and hence the atomic positions in the protein molecule.

The maximum resolution of a protein diffraction pattern, measured in angstroms, is ultimately dependent upon the degree of order within the crystal and controls the amount of atomic detail that can be obtained. As the order within the crystal increases, so does the maximum angle of diffraction, with the spots at greater angles providing higher-resolution information. An increase in resolution results in objects with smaller separations being resolvable. Thus, as resolution increases, the resolution distance, in angstroms, decreases. A perfectly ordered crystal would result in measurable diffraction intensities to the maximum resolution possible, which is equal to the incident X-ray wavelength divided by 2. Proteins, however, are flexible molecules, and thus do not form perfectly ordered crystals. At higher resolutions, the diffracted waves no longer interfere constructively, thus resulting in a loss of intensity, restricting the amount of detail obtainable from the structure. If a crystal diffracts to only a maximum resolution of 6 Å (0.6 nm), helices are visible, whereas β-sheets cannot be identified; at about 2.5 Å (0.25 nm), the side

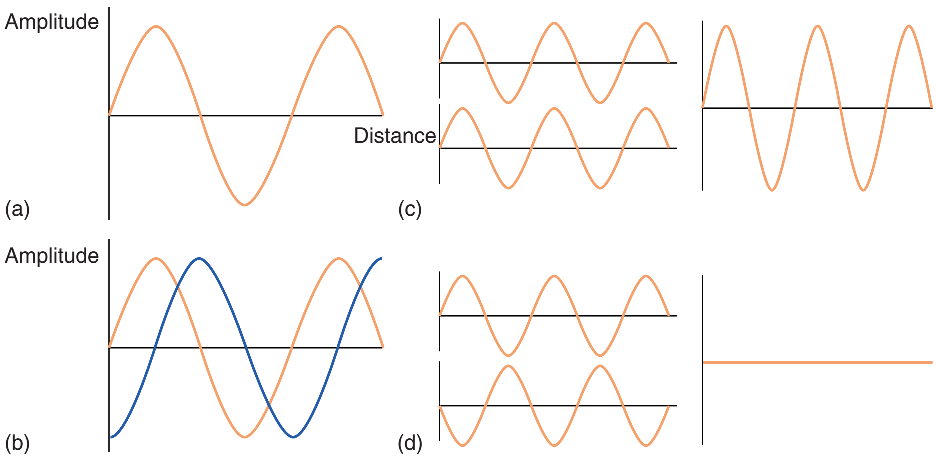

Figure 2 (a) A sine wave. The sine wave can be described in terms of its amplitude *A*, that is, its maximum displacement from zero, and wavelength λ–the distance between adjacent peaks, that is, one whole waveform. (b) Two sine waves. The two waves shown have identical wavelengths and amplitudes. They are not, however, placed identically with respect to the origin, which indicates that the waves are not in phase. The blue wave has one-fourth of a wavelength phase delay from the red one. (c) Constructive interference. The two waves on the left have the same amplitude, wavelength, and phase. If these two waves are combined, the resulting wave will be like that shown on the right: the phase and wavelength will remain the same, while the amplitude will double. This is constructive interference. (d) Destructive interference. The two waves illustrated on the left are one-half of a wavelength out of phase. Combination of these two waveforms will result in the wave on the right, which has an amplitude of zero. This is destructive interference

chains are identifiable, and towards 1 Å (0.1 nm), even hydrogen atoms begin to be visible.

Once diffracting crystals have been obtained, a data set can be measured, whereby a series of diffraction images are collected from the crystal. The crystal is rotated to allow data collection from different orientations so that diffraction intensities will give information about the whole protein molecule. In the case of the light microscope, a lens is used to refocus the diffracted rays. There is, however, no lens for X rays and the reconstruction of the protein structure must be obtained computationally. Unfortunately, the observed diffraction intensities only provide part of the required information. In order to determine the structure of the crystallized protein, both the amplitude and relative phase of the diffracted waves must be known (see Figure 2). The amplitudes of the spots can be calculated from the intensities, since the intensity of a spot is proportional to the square of the amplitude. Identification of the relative phase of each spot, however, is not so straightforward.

There are conceptually three methods that can be used to estimate the phases: one depends upon determining the phases by trial and error, the second estimates the phases experimentally, that is, by the collection of further diffraction data, and the third applies phases from a known structure thought to be similar to the target structure.

The first of these methods – the direct method – is used in small-molecule crystallography, but requires data at resolutions better than 1.2 Å (0.12 nm), and preferably less than 1000 atoms in the structure and therefore cannot be applied to

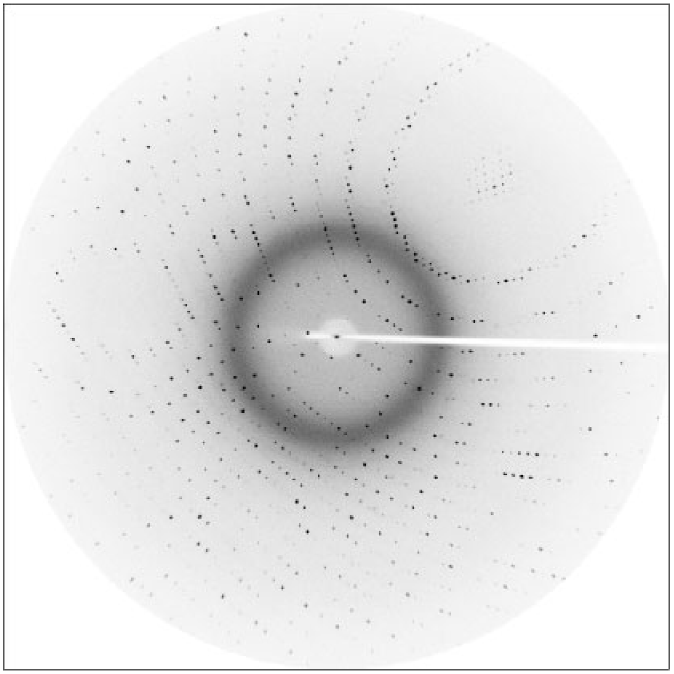

Figure 3 An example of a diffraction image. The individual spots are the result of constructive interference of the X-rays as they are diffracted by the molecules in the crystal. Many such images are required in order to determine the structure of a protein

the majority of protein structures. The second is more commonly used in protein crystallography and depends upon collecting a data set from either an identical or virtually identical crystal. In methods such as multiple isomorphous replacement (MIR), heavy atoms, for example, mercury, are soaked into the crystals, allowing the atoms to bind at specific sites within the crystals. The presence of such heavy atoms, with high electron numbers, perturbs the diffraction intensities. The differences between corresponding intensities in different data sets can then be calculated, enabling estimation of the possible values of the phase angles. A similar approach, multiple wavelength anomalous dispersion (MAD) makes use of anomalous scatterers within the crystal, either native or incorporated, which scatter differently depending on the wavelength of the incident beam. Anomalous scattering results from the absorption and reemission of the X rays by the electrons in the crystal. In light atoms, that is, those in the higher rows of the periodic table, the electron energies are too high to allow excitation of electrons to occur. Thus, the anomalous scattering effect of such light atoms is insignificant. With atoms heavier than sulfur, providing that X rays of a suitable wavelength are selected, the X rays may be absorbed by an electron and then subsequently emitted with a phase shift from the incident beam.

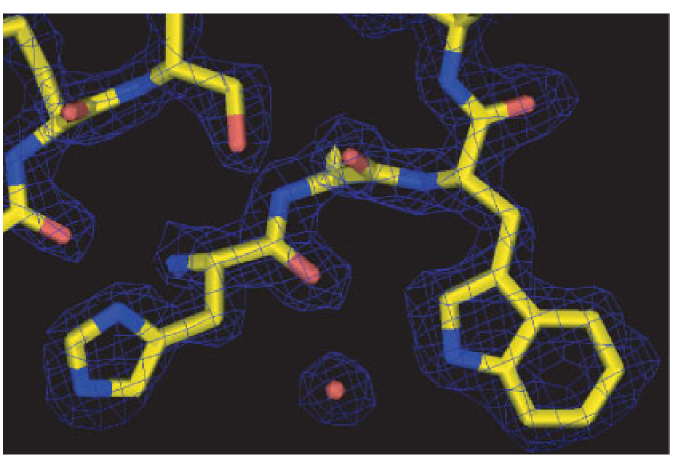
Data collection can be optimized, depending on the particular anomalous scatterers within the crystal, to obtain the maximum difference in scattering behavior

during successive rounds. Again, the differences between data sets can be calculated and used to find an estimation of the phase angles.

The third method, molecular replacement, depends upon the successful prediction that the target structure is similar to that of a known structure. Proteins with high sequence homology usually have a similar protein structure, and if the structure of such a homologous protein is already known, the model can often be fitted to the collected diffraction data and the phases estimated. The success of this method largely depends upon the identification and availability of a structurally similar protein. The method is particularly useful when data is collected from the same protein molecule with a different packing arrangement, or from highly homologous proteins – perhaps from two different organisms.

Following the successful measurement of reflection intensities and estimation of phases, an electron density map can be calculated and examined. The protein molecule can be built into the electron density map (Figure 4), usually with the help of the sequence of the protein. Refinement is then carried out, a process that aims to optimize the positions of the atoms within the model such that they fit with the observed diffraction intensities and estimated phases.

Thus the basic requirements for the determination of a protein structure by crystallography are as follows: a sufficient quantity of pure protein to set up crystallization trials, preferably in the milligram range; diffraction quality crystals; and a method to determine the phases (Scheme 1). Each of these processes can be problematic. The expression of sufficient quantities of protein to allow a high level of purification such that many crystallization experiments can be set up is a fundamental requirement and often the first hurdle to be overcome. Advances in cloning, expression, and purification techniques, along with the application of high throughput methods are fundamental to the pursuit of a structural-genomics approach, but are covered elsewhere (*see* Article 97, **Structural genomics – expanding protein**



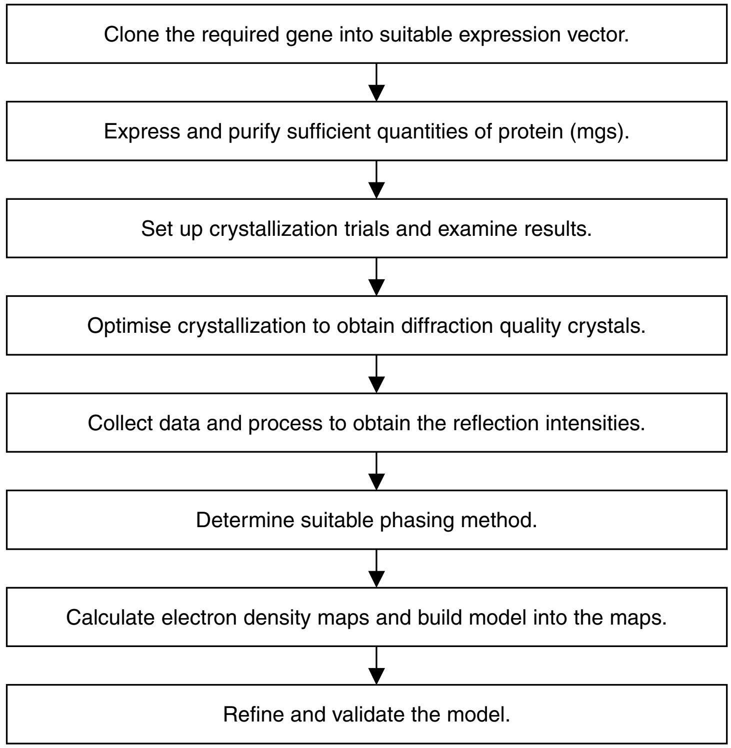


Figure 4 A stick model of the protein is built into the electron density maps, represented by the mesh-like lines. Here a good fit can be seen of the residues within the map; the histidine and tryptophan side chains are clearly identifiable. A spherical water molecule can be seen toward the bottom of the figure, modeled by the small red sphere

Scheme 1 The basic stages of structure determination by X-ray crystallography. At most points, problems may be encountered that force a return to an earlier stage in the procedure

structural universe, Volume 6). At the same time, there is progress in minimizing the amount of protein required. The development of automated crystallization robots has greatly improved the potential for crystallization of a protein. The technology is now available to allow crystallization on a nanoliter scale, thus allowing crystallization experiments with approximately 1000 times less than a classical crystallization trial. The crystallization of proteins is a trial and error procedure, often requiring hundreds of individual crystallization experiments to be set up. With nanoliter scale drops, many more individual experiments can be set up, allowing screening of a much greater range of conditions, thereby increasing the chance of obtaining crystals. Once promising conditions have been identified, they can be optimized, and, if required, scaled up to the microliter range. Robots allow this to be carried out far more rapidly, efficiently, and reproducibly than by hand.

After obtaining crystals, diffraction experiments are required, to determine if the crystals diffract sufficiently or if further optimization of the crystallization is required. If the crystals diffract well enough, then data collection can proceed and a strategy for determining the phases must be established. Since one of the aims of structural genomics is to determine the structure of proteins with novel folds, it is unlikely that molecular replacement, the use of a known structure to estimate phases, will serve as the main phasing tool. With the increase in computational

power, however, molecular replacement routines can be carried out rapidly and increasingly automatically, which raises the potential to search with a large number of structures, even if homology is low. Any high-scoring solutions can then be examined to see if they are likely to provide good phases. Traditional methods – such as the soaking in heavy metals – can be used, but are not so amenable to automation. The use of anomalous scatters is perhaps the most promising automated phasing method. Currently, the majority of proteins requires the incorporation of an anomalous scatterer into the protein during expression, for example, with the replacement of methionine residues with selenomethionine residues. Research is currently underway to enable the phasing of proteins using the anomalous signal from the native protein – that is, from sulfur atoms in side chains, or from phosphate ions. Such methods are ideal for structural genomics, since no additional gene manipulation, soaking experiments, or growth of cells on expensive and toxic selenium media are required, fitting with the high throughput maxim.

A range of programs exist to assist with the building and refinement of the model, once all of these goals have been achieved. Increasingly, with high-resolution and high-quality data, building and refinement can also be largely automated but in many cases this is not the case and the process requires many hours spent working at the computer. There is also the problem that the number of parameters to be fitted generally exceeds the number of observations – that is, those derived from the measured intensities. In order to obtain the best model, therefore, standard geometrical restraints are normally applied during refinement, incorporating realistic values for bond lengths and angles. This enables sensible refinement of the model to be carried out with the limited amount of experimental observations available.

As with any experiment, a form of validation should be carried out. The low ratio of observations to the number of parameters to be fitted can give rise to over fitting of the model – where the model appears to fit the data well, but in fact is incorrect. In order to reduce over fitting, a random subset of reflections is excluded from refinement to act as a control. If the model is built correctly, it should still fit with the excluded subset. A second method to validate the structure is to compare it with other structures: bond lengths and angles are known from small-molecule structures, and the torsion angles found within proteins are mostly found to have a limited range of values as found in the Ramachandran plot. Consistency with such accepted ranges is a good indication that the structure is good.

The determination of a structure, however, may only be the start of the battle in the structural-genomics world. Whilst the function of some proteins can be predicted by sequence analysis, in other cases the function is unknown. Correctly predicting the function of a protein on the basis of its structure is far from straightforward, although some methods are available and they are improving as we learn more about the structure–function relationships of proteins. In some cases, small molecules are copurified and crystallized with the protein of interest, perhaps giving insight into the function. In other cases, the fold of the protein places it in a known class of proteins not predictable from the sequence level. Otherwise, analysis of the structure is carried out in order to identify large clefts that may act as active sites, or particular clusters of residues that could engender functionality

to the protein. The relationship between structure and function is examined more deeply in elsewhere in the encyclopedia.

X-ray crystallography thus holds great potential to assist the characterization of proteins identified by genomics projects. Of course, its more traditional role of elucidating proteins of known function will continue to be fundamental in the understanding of protein function, both in and out of the large-scale genomics projects. Methodology is constantly improving in all aspects of crystallography, from the protein expression level, to data collection facilities, to the validation of structures. It is hoped that, as our knowledge and experience increase, our ability to extract information from structures will also improve, enabling us to gain a full understanding of the proteins within us.

NMR

C. Jeremy Craven
The University of Sheffield, Sheffield, UK

1. Introduction

Solution state Nuclear Magnetic Resonance (NMR) provides an alternative technique to X-ray crystallography (*see* Article 104, **X-ray crystallography**, Volume 6) for the determination of protein structures. NMR has so far proved much less amenable to automation than X-ray crystallography, but it exhibits a number of features that make it highly complementary to the diffraction technique for the determination of structures of small proteins in a high-throughput manner for structural proteomics projects.

2. Basic technique

The signal detected in an NMR experiment arises from the interaction between the nuclei of atoms in the molecule and a very strong applied magnetic field (Figure 1). There is a wide range of possible protein NMR experiments, whose full description is beyond the scope of this article. The rich information content of such spectra arises mainly from three phenomena. First, the frequencies of the signals observed depend upon the detailed electronic environment of the nuclei, which in turn is sensitive to the conformation of the protein molecule. Therefore, information can be obtained as to whether the protein is folded or unfolded, or whether a conformational change has occurred. Unfortunately, the dependence of the chemical shift upon conformation is so complex in proteins that it has not proved possible to obtain extensive information for structure *determination* from this property. (Chemical shift *changes* that occur upon binding of a ligand are, in contrast, particularly informative in probing interactions of proteins with macromolecular or small molecule ligands.) The second phenomenon is that the frequency of the NMR signal from a particular nucleus can be sensitive to the spin state (i.e., parallel or antiparallel to the magnetic field) of neighboring nuclei to which it is chemically bonded. This phenomenon, known as *scalar coupling*, is particularly useful during the procedure of assigning NMR signals to particular nuclei in the molecule, since it enables signals to be linked together into bonded networks that can be matched to the covalent structure of the molecule. Third, nuclei can influence each other owing to the interaction of the magnetic moment

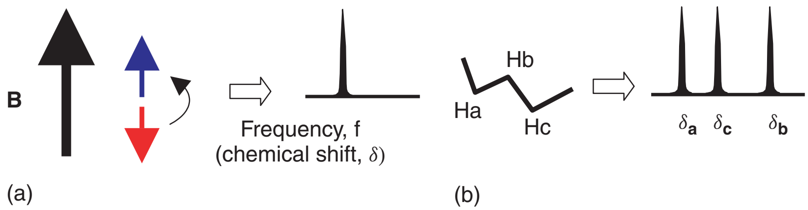

Figure 1 The basic phenomenon of NMR. (a) In a very strong applied magnetic field B, spin 1/2 nuclei (in proteins: ^{1}H, ^{15}N, ^{13}C) align parallel (blue spin) or antiparallel (red spin) to the applied field. The essence of the simplest one-dimensional NMR experiment is to perturb the distribution of spins between these two energy levels by applying a radiofrequency magnetic field. Radiofrequency electromagnetic radiation is emitted as the spins make transitions between the two energy levels and return to thermal equilibrium. The detected radiation can be represented as a peak at a particular frequency, or *chemical* shift, in a one-dimensional NMR spectrum. (b) The chemical shifts of the signals depend upon the precise strength of the magnetic field experienced by a nucleus, which depends, in turn, upon the extent to which it is shielded by its surrounding electrons. In a molecule containing three chemically distinct hydrogen atoms, three signals would generally be observed in the ^{1}H NMR spectrum

of one nucleus with the small magnetic field generated by the magnetic moment of another nucleus that is nearby in space. In solution state NMR, this affects the *relaxation* rates of nuclei, for instance, the rate at which nuclei return from an excited state antiparallel to the magnetic field to the ground state parallel to the magnetic field. This through-space (as opposed to through-bond) process also gives rise to the nuclear Overhauser effect (NOE), which provides the primary information for structure determination by NMR, since it indicates which nuclei are close in space due to the 3D fold of the protein. The NOE, which is fundamentally a relaxation phenomenon, is the change in intensity of an NMR peak due to the perturbation of the populations of the energy levels of a nearby nucleus.

3. Sample requirements

Protein molecules comprise such a large number of atoms that a simple, one-dimensional spectrum of the signals arising from all the hydrogen nuclei is too complex to interpret. The most efficient method to alleviate such an overlap is to incorporate the stable isotopes ^{15}N and/or ^{13}C into the protein to allow the use of multidimensional methods (see below). Such incorporation is straightforward to achieve in overexpressed proteins, by limiting the nitrogen or carbon sources to labeled compounds such as ^{15}N ammonium salts and ^{13}C glucose. Labeling with ^{15}N is sufficiently inexpensive and useful to be routine at the early stages of a project. Labeling with ^{13}C is an order of magnitude more expensive, and is generally only justified once a protein has been selected for structure determination.

A typical sample for structure determination by solution state NMR consists of a solution of 300–500 µL of 0.2–2 mM protein dissolved in water. This corresponds to ca. 1–20 mg of a 20-kDa protein. The protein must be soluble, robust, and pure enough to remain in such solution for a period of at least 1 week, and preferably

longer, although in cases of rapid degradation, multiple samples can be used. As for X-ray crystallography, the protein must be well folded, and if there exists any posttranslational modification, then such modification should be uniform within the sample.

4. Size limitations

There are two factors that limit the size of proteins that can be studied by NMR. The first is that the number of signals in an NMR spectrum is proportional to the size of the protein; overlap of these signals can make the spectrum too complex to interpret, even with isotope labeling. The second factor is that the rate of Brownian molecular tumbling in solution has a large effect on the sensitivity of NMR spectra. In general, larger proteins tumble more slowly than smaller proteins, which, for reasons beyond the scope of this article, leads to a reduction in sensitivity of NMR spectra. These factors dictate that full structure determination is relatively straightforward for well-behaved proteins less than about 180 a.a. (20 kDa).

The tumbling rate of proteins is sensitive not only to the molecular weight (and, to a lesser extent, the molecular shape) but also to the aggregation state. For instance, a protein that is dimeric will tumble with the characteristics of a protein of twice the molecular weight. In the case of physiological "true" dimers, this is unavoidable. The most problematic cases can be where nonspecific aggregation at the high concentrations required for NMR gives rise to spectra of a much poorer quality than expected for the monomeric molecular weight. It is not uncommon that proteins are simply insoluble at these high concentrations, or precipitate over a timescale of a few days.

5. Sample screening by ^{15}N HSQC

The detailed topic of multidimensional NMR is beyond the scope of this article; however, one particular spectrum, the ^{15}N HSQC spectrum, is worthy of detailed mention since it is the major tool for protein characterization at the early stages of many structural proteomics programs by both NMR and crystallography. An example of such a spectrum is shown in Figure 2.

In the screening stage of a structural proteomics program, this spectrum would indicate several very important things about the behavior of this protein. First, it shows that the protein is folded since the signals are well spread out, or *dispersed*, in the hydrogen dimension. Such dispersion arises from the fact that in a well-folded protein, the different amide groups along the protein backbone experience distinct environments. In an unfolded or molten globular protein, the environments will, on average, be much more similar to each other, and the signals would be observed to cluster much more tightly around the center of the range. Second, the correct number of signals are observed for the number of residues in the protein, indicating that structured parts of the protein are not undergoing slow conformational or intermolecular interactions that would either attenuate some signals or cause several peaks to be observed for one residue. The signals are also relatively sharp, which

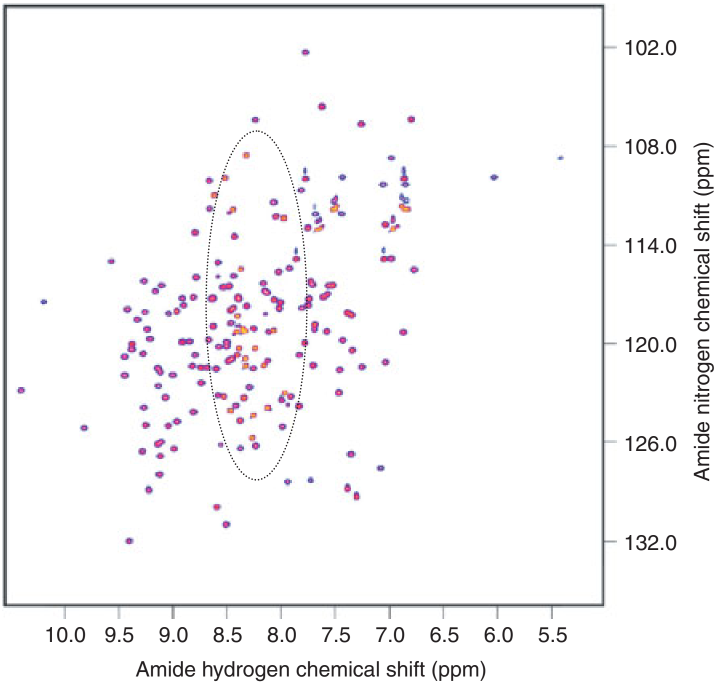

Figure 2 ^{15}N HSQC spectrum of the 19-kDa protein TCTP from *Schizosaccharomyces pombe*. A ^{15}N HSQC spectrum is a two-dimensional spectrum in which the frequencies of directly bonded ^{1}H–^{15}N pairs are simultaneously measured. One signal, or *crosspeak*, is observed for each NH group in the protein. Since the position of each crosspeak is determined by the frequency of the signal from both the ^{1}H and ^{15}N nuclei, the problem of overlap of the hydrogen frequencies is much reduced. The dotted line marks the area containing many intense and sharp peaks with ^{1}H shifts characteristic of unfolded proteins

indicates that the protein has suitable tumbling characteristics. Finally, the spectrum contains about 20 very sharp and intense signals clustered around the centre of the hydrogen dimension. Such signals are characteristic of a portion of the protein being unfolded. This is not a particular problem for an NMR structure determination, provided it does not have a severe effect on slowing the molecular tumbling. It would, however, often be problematic for crystallization of such a protein, in which case it would be necessary to identify the mobile residues involved and make constructs that eliminate these residues. Where alternative constructs are made, NMR provides an efficient method to test whether the construct indeed removes the mobile residues, and also whether the fold of the protein is retained. Note that HSQC screening is feasible for proteins up to approximately twice the size for which full structure determination is possible.

In cases where a poor HSQC spectrum is obtained, it is possible to screen alternative buffer and temperature conditions. Alternatively, the screening of orthologous proteins has been shown to increase the proportion of proteins for which a satisfactory HSQC spectrum can be obtained (Savchenko *et al*., 2003).

6. Structure determination by NMR

Once a ^{15}N HSQC spectrum of adequate quality has been obtained, the procedure for determining a 3D structural model of a protein is fairly straightforward, and can be obtained on average in about 2–6 months of a single person's effort. The first stage is to assign the different NMR signals observed to particular nuclei in the molecule, a process known as resonance assignment. This is followed by the derivation of distance restraints from NOESY spectra (Figure 3). Given enough such distance restraints, well-established computational techniques allow the derivation of a 3D model of the protein. Typically, the structure is calculated using molecular dynamics (Figure 4), in which extra energy terms are included to implement the distance restraints.

One particular problem in obtaining structural information from NOESY spectra is that overlap of chemical shifts can make it difficult to establish unambiguously which pair of atoms gives rise to a particular crosspeak. Therefore, the normal procedure is first to calculate a low-precision structure, using distance restraints only from crosspeaks that are readily assigned. Ambiguous crosspeaks can then be reexamined, and assignments incompatible with this preliminary model can be eliminated. By thus incorporating additional restraints, the precision of the structure can be iteratively improved. Some progress has been made in semiautomating this process by software packages such as ARIA; however, it remains the single greatest impediment to more rapid structure determination by NMR. While distance restraint data remains very much the primary source of NMR structural data, the structure calculation can be supplemented with torsional angle data from chemical shifts or scalar couplings, and with more global restraints from residual dipolar couplings or paramagnetic ion effects.

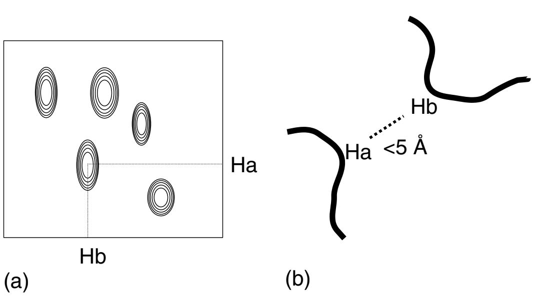

Figure 3 NOESY spectrum and distance restraints. The crosspeaks in a NOESY spectrum (a) occur for pairs of ^{1}H nuclei that are closer in space than about 5 Å. The simplest NOESY spectrum is a two-dimensional spectrum in which the position of crosspeaks is determined by the chemical shifts of the two nuclei involved. The observation of a crosspeak linking the frequencies of two nuclei Ha and Hb indicates that these two nuclei are close in space (b). If the two nuclei are far apart in sequence in the protein, this provides a powerful *distance restraint* from which the 3D structure can ultimately be calculated. Even with multidimensional techniques, such spectra are very complex and the extraction of the data from these spectra, therefore, remains a very challenging problem, which requires significant human input

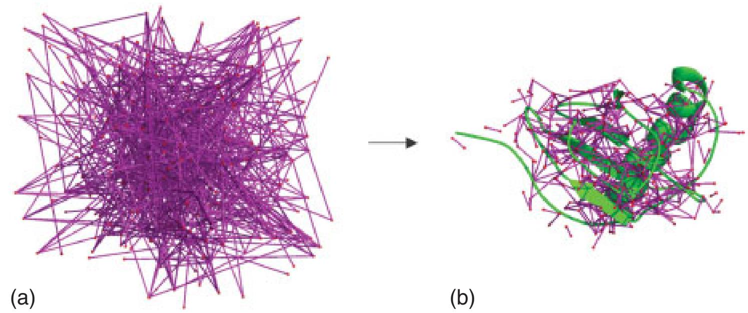

Figure 4 Structure determination by NMR. In one implementation of a molecular dynamics–based structure determination by NMR, the atoms of the protein are initially placed randomly (a). The distance restraints (represented by the magenta lines in (a)) can be visualized as taut "elastic bands" between the atoms. The atoms are then allowed to move under the influence of these restraints, and also subject to bond lengths and bond angles dictated by the covalent structure of the protein. The atoms move to satisfy the restraints to create a 3D model of the protein (b). By starting from different sets of random starting coordinates, an ensemble of structures can be determined, all of which satisfy the distance restraints, from which an estimate of the precision of the model can be made. For clarity, intraresidual restraints have been omitted, and only atoms to which restraints have been determined are shown individually. The protein shown is the 11-kDa cysteine proteinase inhibitor, human cystatin A

7. Complementarity to X-ray crystallography

In highly automated proteomics projects, one might expect X-ray crystallography to dominate owing to its much more automated structure determination methods. One of the advantages of NMR over X-ray crystallography is that, once purified recombinant protein is obtained, screening for suitability for further study can be achieved very rapidly by the ^{15}N HSQC method discussed above. Furthermore, this early screening is very strongly diagnostic: if the screening result is favorable, then a structure can be more or less guaranteed within a well-defined timescale. This contrasts with the much greater uncertainty in the timescale for the production of crystals that diffract well. Thus, it has been argued (Savchenko *et al*., 2003) that NMR may represent the most efficient strategy for structural proteomics of small proteins.

This conjecture appears to be supported by the distribution of structures that have been deposited so far (Figure 5). It, therefore, appears that the ability to rapidly screen and select targets for NMR enables it to remain a competitive technique for the structure determination of small proteins, even in the context of highly automated proteomics programs. In addition, NMR also provides an excellent route for screening small protein targets for *both* NMR and X-ray crystallography in order to optimize the constructs that proceed through to the structure determination stage, therefore greatly increasing the number of successfully studied small proteins by either technique.

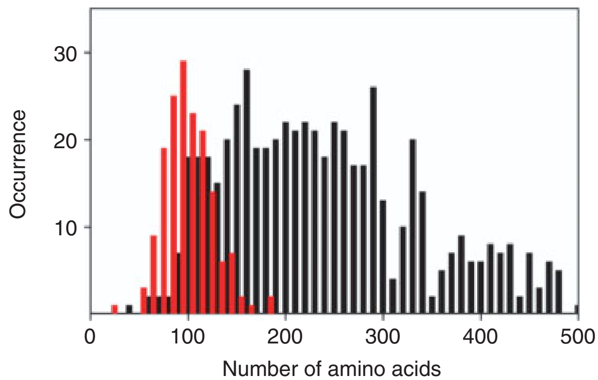

Figure 5 Distribution of protein structure determinations in structural proteomics programs, determined by NMR (red) and X-ray crystallography (black). The data was extracted from **targetdb.pbd.org**. These distributions are affected by the scale of resources dedicated to the two techniques, and also by the relative difficulty of crystallizing small proteins, especially if they are domains of larger proteins. It is markedly different from the distribution of structures deposited in the PDB as a whole, where, for proteins of size 50–120 a.a., there are approximately twice as many entries for structures determined by X-ray compared to those determined by NMR (**http://oca.ebi.ac.uk/oca-bin/ocamain**)

Electron microscopy as a tool for 3D structure determination in molecular structural biology

Neil A. Ranson
University of Leeds, Leeds, UK

1. Introduction

In recent years, electron microscopy (EM) has been elevated from a tool for studying ultrastructure and the *morphology* of large protein assemblies, into a tool for studying protein *structure*. These advances have been made possible by the introduction of novel methodologies, and by dramatic improvements in instrumentation and computing resources available to researchers.

2. EM image formation

With the small apparent wavelength of high-energy electrons (~0.025 Å at 200 kV), a modern electron microscope is potentially an excellent tool for protein structure determination. However, many physical and optical considerations limit the resolution that can be obtained in practice.

First, electrons are focused in an EM as they move through a magnetic field, rather than a traditional lens. Such "magnetic lenses" are imperfect, and these imperfections mean that the focused beam must be passed through a small aperture; a small (~40 μm) hole in a metal foil, which excludes highly scattered electrons and prevents their contributing to the image. The use of a small aperture, just as in photography, limits the attainable resolution (to ~1 Å in this case). It also gives a large depth of field, meaning that all objects in the image are at approximately the same level of focus, and this has profound consequences for the interpretation of EM data that are discussed below. Secondly and more importantly, the EM image recorded is a combination of elastic scattering events (which generate information from the specimen), and inelastic scattering events (which damage the specimen and generate noise). Typical inelastic collisions between electrons and the specimen are actually less damaging than for X rays, but the scattering cross section for electrons is vastly greater. Radiation damage is therefore of primary importance in EM of biological specimens. Such damage is a fundamental limit on the type of biological

specimens that can be examined, as they must be thin enough to prevent multiple scattering events (typically less than 2000 Å). Radiation damage also limits the attainable resolution as limiting dose results in noisy images that are difficult to analyze.

Thin, biological specimens typically scatter electrons very weakly. This means that, somewhat counterintuitively, when the microscope is precisely in focus, very little can be seen as there is almost no contrast. Phase contrast is introduced through a combination of imperfections in the magnetic lenses used, and by the user defocusing the system. In such conditions however, the image observed is modulated by a contrast transfer function (CTF). The CTF is an oscillating function of increasing frequency and decreasing amplitude, which describes the transfer of information within the microscope as a function of resolution. An EM image therefore has alternating bands of positive and negative contrast as resolution increases, and the positions of these bands are dependent on the defocus at which the image was recorded. In practice, this has the effect of grossly distorting the image. Structural information can only be restored by a computational correction of the CTF in the observed, digitized images, and by combining information from images taken at different levels of defocus. This last point is critically important: as the CTF oscillates between positive and negative contrast; at the point where the contrast flips, there is no information at all. The resolutions at which these reversals occur are dependent on defocus, and so combining data at a range of defocus ensures that there is information at all resolutions. The CTF also describes the falloff in information as resolution increases, that is, there is very little signal at the high resolutions needed to reconstruct protein secondary structure. This phenomenon is fundamental to electron microscopy but its effects are ameliorated by the use of field emission gun (FEG) microscopes. For a review of this subject, see Hawkes and Valdrè, 1990 and Saibil, 2000.

3. Basic imaging methods

Isolated protein complexes have traditionally been imaged by using heavy metal staining on continuous carbon (or other) support films. Such an approach has compelling advantages as the stain coats (and to some extent penetrates) the biological molecule, and dramatically enhances both sample stability in the electron beam and the contrast that is attainable in the resulting images. However, a number of profound disadvantages exist. The preparation method presents the specimen with a series of extremely nonnative environments, typically resulting in a somewhat dehydrated specimen with an ~30% flattening against the support film. In addition, the nature of the stains used means that it is actually the stain shell, rather than the biomolecule itself, that is imaged. Finally, the granularity of such stains, and their lack of penetration into biomolecules, ultimately limits the meaningful information obtained to > ~20-Å resolution. Despite these limitations, the low-resolution information obtainable from staining methods has made, and continues to make, an enormous contribution to biology that cannot be underestimated (see for example Burgess *et al*., 2003).

A new EM method for studying biomolecules was pioneered in the late 1980s by Dubochet and colleagues at EMBL, in which specimens were stabilized by

low temperatures (Dubochet *et al*., 1988). Such "Cryo-EM" methods involve placing a solution of the biomolecule in question on to an EM grid bearing a holey carbon support film. Excess liquid is removed by blotting, leaving a thin aqueous film suspended in the holes. This is then cooled *extremely* rapidly by plunging into liquid ethane cooled to near–liquid nitrogen temperature. The enormous thermal conductivity of liquid ethane, and the thinness of the aqueous film (typically <2000 Å) allows vitrification of the solution into a glasslike state, and the biomolecule is trapped in a frozen-hydrated state. Such vitrified specimens have compelling advantages for structural biologists. First, the native structure of the specimen is preserved within the vitreous ice layer, even in the vacuum of the microscope column. Second, observing the specimen at such low temperatures significantly slows radiation damage, and while such damage still fundamentally limits the dose that may be used, usable images of unstained specimens can be recorded. Although such unstained images have extremely low contrast, the native structure of the specimen is preserved and internal structural details of the object recorded. The attainable resolution thus becomes limited only by the homogeneity of the specimen, and the quality of images recorded.

4. Data analysis

Two considerations dominate the analysis of any EM data with the aim of solving the three-dimensional structure of biological macromolecules. First, the large depth of field discussed earlier, together with the penetrating nature of high-energy electrons results in the electron-scattering potential of the object being projected onto the 2D plane of the image. The images obtained are therefore *projection images*, analogous to the familiar images from medical X rays. The 3D structure of an object can be obtained from a set of such projection images only if different views of the object, and their relative orientations, are available. Second, in order to limit radiation damage to acceptable levels, the dose used to record images is limited. This results in the observed images having an extremely poor signal-to-noise (S/N) ratio, and necessitates the use of averaging techniques to combine data from different images and improve S/N. The way in which these considerations are handled depends in large part upon the geometry of the specimen under study.

2D arrays of membrane proteins are particularly well suited to study by EM. Crystalline arrays by definition have a large number of individual molecules oriented by the crystal lattice, which satisfy the requirements for averaging, and mean that the biomolecules are identically oriented (or at least nearly so). In such studies however, different views of the crystalline material are achieved by tilting the specimen inside the microscope, and the maximum tilt angle that can be achieved is $\sim 70^\circ$. This results in a missing wedge of information in Fourier space, and corresponding nonisotropic resolution in the resulting model (with resolution generally poorer perpendicular to the plane of the membrane). Nevertheless, such methods have now resulted in density maps for a number of different membrane proteins in which the majority of the polypeptide chain can be unambiguously assigned. Indeed, the first atomic resolution structure of a membrane protein was determined by EM, in a study that exploited the fact that bacteriorhodopsin occurs in naturally crystalline patches of membrane (a number of studies, culminating

in Henderson *et al*., 1990). Subsequently, a number of artificially crystalline molecules have been determined to similar resolutions, including a plant light harvesting complex (Kuhlbrandt *et al*., 1994), and the cytoskeletal protein tubulin (Nogales *et al*., 1998).

Helical assemblies are also well suited to study using EM. In a helical assembly, a range of angular views of the asymmetric unit is displayed as the helical axis is traversed. Tilting is therefore not usually required for 3D reconstruction. However, order within the helix is generally lower (i.e., variable pitch and twist) than in 2D crystals, and the number of asymmetric units imaged is generally far lower. Despite this, recent work on an exceptionally well-ordered bacterial flagellum has yielded atomic resolution information using helical processing (Yonekura *et al*., 2003). Helical techniques are also extremely powerful when membrane proteins form (or can be made to form) tubular crystals. In such a case, the structure of the nicotinic acetylcholine receptor has been determined to ∼4.5 Å (Miyazawa *et al*., 2003).

It is perhaps in the study of true single particles using cryo-EM that the most visible progress has been made in recent years. The term *single particle* is used to cover any structures that are not part of a higher order assembly. Single particles range from highly symmetric structures such as icosahedral viruses (although some purists insist that icosahedral structures are not true single particles owing to their high symmetry), to objects with no intrinsic symmetry such as the ribosome. Single particle approaches generally rely on the intrinsic randomness of the frozen-hydrated specimen to give randomly oriented biomolecules. A full sampling of molecular views is therefore possible without specimen tilting. Many different approaches in analyzing such data are possible, but in essence they all share the common goals of determining the orientation of the images with respect to each other, and averaging of molecular views in the same orientation to improve S/N (for a comprehensive description, see Frank, 1996; Van Heel *et al*., 2000).

Single particles in solution, with their lack of externally imposed order, are inherently challenging structural projects, and to date no true single particle has been solved with sufficient resolution to unambiguously assign a polypeptide chain. A great many projects are currently in the 6–10 Å range. The most conspicuous progress has been seen in an explosive increase in our understanding of ribosome function (for the review, see Frank, 2003).

5. Synergy with other structural methods

The intermediate (6–12 Å) resolutions generally achieved with EM methods yield models of biomolecules that contain vast amounts of information, but are extremely difficult to interpret. The availability of atomic resolution coordinates of components of an EM map, or of related structures, can dramatically increase this interpretability. The fitting of atomic coordinates into intermediate resolution EM density maps is now routinely used to produce "pseudo-atomic" resolution models that greatly enhance the interpretability of EM data. For example, fitting of the crystal structure of the molecular chaperone GroEL in its unliganded state, into EM density for a GroEL:ATP complex, allowed a detailed description of ATP-induced conformational change (Ranson *et al*., 2001). This description was sufficiently

accurate to allow design of specific point mutations affecting the cooperativity of ATP binding.

6. Current state-of-the-art and future prospects

Spectacular progress has been made in recent years, and will continue into the future. We are, however, approaching a point in time where instrument quality, processing methods, and computing power will be sufficient to give resolutions that approach the homogeneity of the samples that can be prepared for microscopy. EM techniques determine solution structures, where the ensemble of conformations present is specimen-dependent. The attainable resolution will therefore vary from atomic resolution for exceptionally rigid or well-ordered specimens, to perhaps 50 Å or poorer for more dynamic or flexible ones. In addition, the relationship between resolution and the quantity of data required to attain that resolution is decidedly nonlinear: a 10-Å map might require 10^4 images, while a 6-Å map might need 10^5. Especially given the obvious synergy with X-ray crystallography and NMR, perhaps the most powerful application of EM is in studying conformational change in large assemblies, rather than as a tool for atomic resolution structure determination.

Introductory Review

Integrative approaches to biology in the twenty-first century

Marvin Cassman
Consultant, San Francisco, CA, USA

Systems or integrative biology has become wildly popular in just the past few years. (The two terms will be used interchangeably to refer to the quantitative analysis of biological networks, at whatever level of organization.) The reason is clear – the volume of experimental data generated by genomics and other high-throughput techniques pose both a problem and an opportunity. The problem is that the mass of data overwhelms the ability to intuitively understand it. The opportunity is that the data may be able to be manipulated in a manner that allows for an unprecedented understanding of the integrated behavior of biological systems. The mechanistic studies that have generated an amazing ability to decipher the molecular workings of individual biological molecules can now be linked to computational approaches, which will illuminate the functions of tightly coupled and highly regulated biological systems. At the end, the processes underlying health and disease will be understood in greater depth than has previously been possible.

Although there are frequent comments that there is no good definition of systems biology (Henry, 2003), this is somewhat of an overstatement. It is generally agreed that the availability of detailed information from the genome, proteome, metabolome, ad nauseome, has provided an opportunity to understand biological phenotype in a way that has not been previously possible. Many of the initial, and current, attempts to predict phenotype focus on the prevailing paradigm of the past 40 years – single gene defects. This extraordinarily powerful approach has been the major contributor to an understanding of the function of individual genes and proteins. It seems less likely that it can yield an understanding of complex biological behavior, from cellular activities such as motility to the operation and integration of organ systems. Indeed, the excitement surrounding systems biology derives from the underlying assumption that phenotype is governed by the behavior of networks, rather than simply the consequence of individual gene action. It is also assumed that to understand the behavior of complex (or even simple) networks, computational approaches will be required. It is worth a short digression to see how this variant fits into the spectrum of what is broadly referred to as “computational biology”.

Computational biology is not new and is not even one thing. Computational chemistry is what most people have meant when they refer to computational

biology. It is a long-established and well-understood area that involves computation on the molecular level, such as protein folding, molecular dynamics, and small-molecule docking. Another more recent form of computational biology is computational genomics, the offshoot of the genome programs, and the most common variant of bioinformatics. This is a discipline that is of more recent vintage than computational chemistry and is now very well appreciated. It involves storage, retrieval, and analysis of information from large data sets. Perhaps the oldest variant of computational biology is computational physiology, which can be traced back at least as far as the Hodgkin–Huxley equation in 1947. This form of computational biology involves the development of quantitative models that describe the behavior of physiological systems. The newest version is computational cell biology, which primarily involves the analysis of cellular networks through modeling and simulation, with targets such as signal transduction networks, cell motility, and cis-regulatory controls on the gene. (Let me say that I realize that there are other variants of computational biology that I have not included, such as epidemiology, population genetics, and computational neuroscience. My apologies to these and others.)

The heart of integrative/systems biology is the use of computational tools for modeling and simulation when applied to cellular and organ systems. Coupled to this are the tools that are required to construct the networks, which include the approaches of computational genomics and proteomics.

Modeling and simulation have a long and honored history in most of the sciences, but not in much of modern biology, and certainly not in modern cell biology. The reasons for this are complex, but at least in part, derive from moving from the concept of a cell as a fuzzy and ultimately unknowable unit of infinite complexity to the cell as defined by finite and understandable molecular elements governed by the laws of chemistry. In the process, the idea that cellular phenotypes were emergent properties that result from complex interactions was largely discarded. In its place came the purely mechanistic concept of the cell as little more than an assemblage of loosely linked molecular devices. On the whole, this was a change decidedly for the better. “Emergent properties”, after all, sounds much like a new-age mantra that should be associated with bland music and pyramids. More importantly, the rigorous application of chemical principles has allowed an understanding of biological specificity and its consequence, the ability to design specific interventions. However, the mass of information that has been generated in recent years has forced a reconsideration of the need to apply computational models to biological systems. Nowhere has this been more apparent than in the analysis of cellular regulatory networks. Decades of research have led to the kinds of connectivity diagrams shown in Figure 1. These networks predominate in living cells and particularly in eukaryotic cells, which are differentiated from their simpler brethren, not so much by the pathways of metabolism, which tend to be relatively similar, but by the increase in regulatory controls. Within eukaryotes, humans are overrepresented in gene functions related to signaling networks, both intra and extracellular. It is clear that the input–output relationships and the effects on phenotype of variation in their components, for networks such as that shown in Figure 1, cannot be understood intuitively. Computational modeling and subsequent experimental verification of in silico–predicted behavior are required to understand the behavior of such systems.

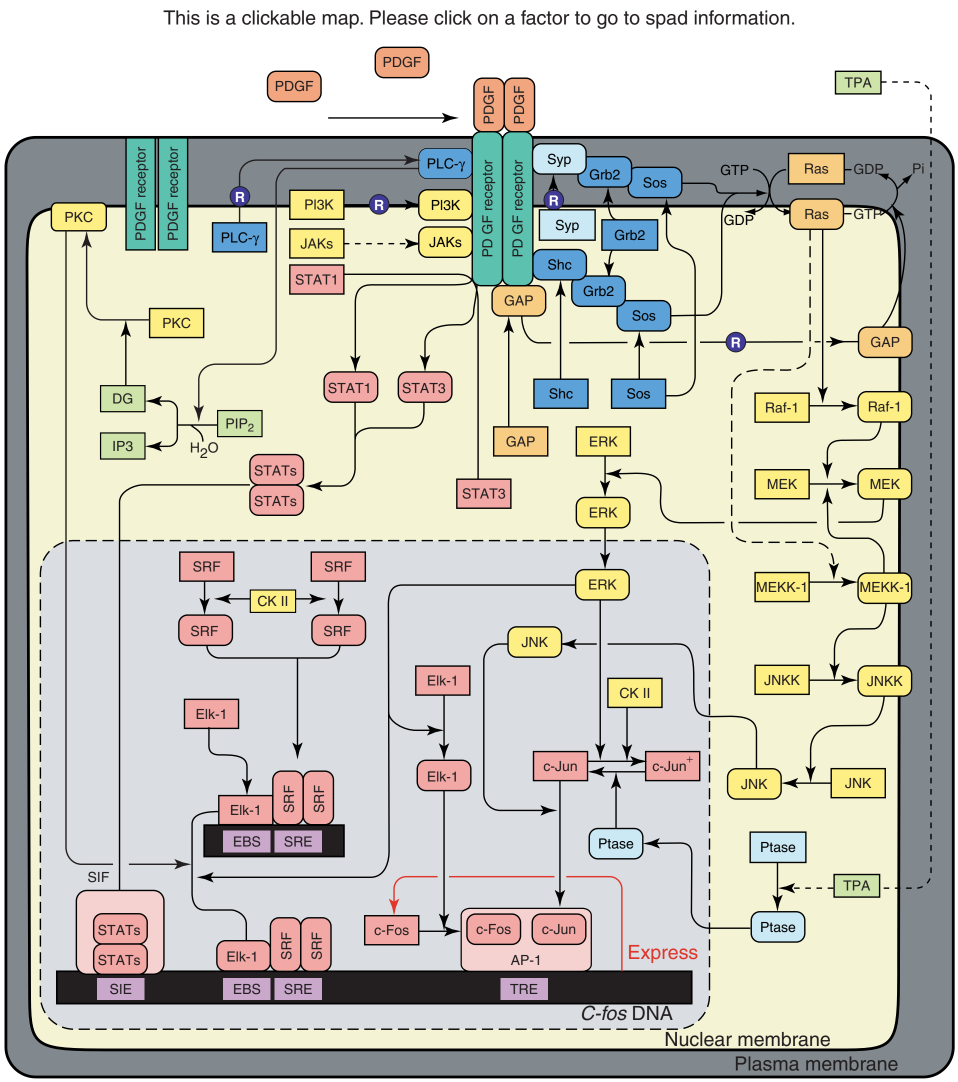

Figure 1 Signaling pathway mediated by PDGF (Reprinted with permission from Satoru Kuhara, Kyushu University, Japan)

How can we begin to deal with networks of such complexity, much less extend them into higher levels of organization such as organs and organ systems? As always, it is useful to begin with a simplifying hypothesis. (Although data-driven research may yield information, it still requires a hypothesis to generate knowledge.) This is an extension of the hypothesis stated earlier: Phenotype is governed by modular systems of complex networks whose output is highly resistant to change. This hypothesis brings into focus two important and somewhat controversial concepts – modularity and robustness. What can we say about these, and why are they important?

Biological modules have been defined in a number of ways. One is purely operational – the identification of groups of genes that tend to respond in a joint manner, for example, through temporally coordinated gene expression (Segal *et al*., 2003). Another is the identification of discrete groups of interconnected elements that are abstracted from the topology of the network (Wuchty *et al*., 2003). Yet a third functional definition is a set of genes and gene products that perform some task nearly autonomously (von Dassow *et al*., 2000). One example of the latter is the set of proteins involved in bacterial chemotaxis, which has been modeled by Leibler, Bray, and others (Barkai and Leibler, 1997; Morton-Firth *et al*., 1999; Yi *et al*., 2000).

The necessity for identification of modules is simple – the cell is too complex to be modeled as a whole. Of course, this is a problem for humans, but not necessarily one in which nature is obliged to accommodate us. Luckily, it appears that modular networks as well as network motifs are common in nature and may even be a natural consequence of evolution (Hartwell *et al*., 1999). However, a major problem remains – the identification of modules and their boundaries. In this effort, genomic, topological, and functional approaches will all be needed.

A second issue is that of robustness. One definition of robustness was given by Waddington (1942) as "canalization" – the constancy of phenotype in the face of genetic and environmental perturbation. On a molecular level, it can be defined as the insensitivity of network output, that is phenotype, to variation in system parameters. Evidence for robustness has been found in the analysis of a number of networks (Barkai and Leibler, 1997; von Dassow *et al*., 2000; Lee *et al*., 2003). Further, the evolution of complex networks has been suggested by Siegal and Bergman (2002) as the driving force for "canalization". Nevertheless, the question remains – robust in regard to what? For bacterial chemotaxis, it is in the regulation of a switch that rotates the bacterial flagellum in one direction or another (Barkai and Leibler, 1997). In *Drosophila* development, it is moving from one developmental state to another (von Dassow *et al*., 2000). However, not all phenotypic characteristics are equally insensitive to parameter change. For example, in bacterial chemotaxis, the rate constant for the flagellar switch is very sensitive to parameter variation (Barkai and Leibler, 1997). This raises the obvious question as to how and why some systems might evolve to a robust phenotype while others are appropriately more plastic and responsive to the environment (Marder and Prinz, 2002; Cassman, 2003).

Apart from regulatory networks, metabolic pathways are pervasive and highly conserved across organisms. The analysis of these networks is sometimes referred to as "metabolomics". Modeling of metabolic pathways has a long history, dating to the development of metabolic control analysis (MCA) in the 1970s (Kacser and Burns, 1973; Heinrich *et al*., 1997). More recently, flux-balance analysis (FBA), which assumes a steady state and a known stoichiometry of reaction, has been developed and applied on a genome-wide scale (Famili *et al*., 2003) and has been able to make in silico predictions that are consistent with some in vivo observations. Robustness can be observed in these approaches as well, since Edwards and Palsson have been able to show that the *E. coli* metabolic network is insensitive to large changes in a set of critical gene products (Edwards and Palsson, 2000). Modularity in metabolic networks has also been demonstrated by Barkai and her colleagues,

who have shown that in the yeast *S. cervisiae*, examination of gene coexpression showed a hierarchical organization of metabolic pathways into groups of varying expression coherence (Ihmels *et al*., 2004). A similar nested hierarchy of modules was also found from topological analysis (Ravasz *et al*., 2002), although there were significant differences between the two hierarchical trees.

As we move up in complexity, modeling of physiological functions such as action potentials in the heart, calcium flux, and the operation of neuronal circuits have been attempted at various levels of integration. Modeling the heart has linked cell studies with detailed anatomical models to produce some remarkable results (Kohl *et al*., 2000), including the mechanism of arrhythmogenic effects of sodium channel mutations (Noble, 2002). Several systems have been used to generate computational models of calcium flux (Sherman *et al*., 2002). Here again the various transport and cellular regulatory mechanisms have been treated as independent modules and then combined to establish a cellular process with specific phenotypic properties, in particular the oscillations that are characteristic of cellular calcium concentrations.

Robustness can be also be observed at these more complex levels of organization, albeit through a somewhat different mechanistic process than we have identified thus far. In neurons, conductances and activity patterns must remain stable in the face of ongoing processes of degradation and synthesis of ion channels. Models have shown that synapses do not have to be perfectly tuned to generate acceptable physiological outputs and that different initial synaptic strengths will result in similar network dynamics (Marder and Prinz, 2002).

At this point in the development of biological modeling and simulation, what is most interesting are the questions. What constitutes a module and the existence of and mechanism(s) underlying robustness are only two of these? What detailed information is minimally necessary to model cellular systems? Are there characteristic design elements in biological networks, and do the global properties of these networks fit some common structure, that is, scale-free (Barabasi and Albert, 1999)? What are the system characteristics that allow plasticity and which convey stability and how are these balanced? These and other questions will be addressed in the next few decades and their answers will enhance our knowledge and improve our ability to manipulate biological systems for the benefit of humanity.

Specialist Review

Functional networks in mammalian cells

Yuguang Xiong and Ravi Iyengar
Mount Sinai School of Medicine, Department of Pharmacology and Biological Chemistry, NY, USA

1. Introduction

The mammalian cell is a complex system composed of many types of components ranging from simple inorganic molecules to complex macromolecular assemblies that form organelles. The complexity of mammalian cell arises from the large number of molecular components contained in the cell, the complex interactions between these cellular components, and the anisotropic spatial distribution of the components within the cell. The identity of the mammalian cell is defined by its genetic makeup. Gene expression programs allow for the transcription and translation of specified genes such that the expression of key proteins defines the phenotypic behavior of the cell. However, both the genetic code and the protein products are subject to changes: genetic codes can be altered by mutation caused by normal physiological or pathological conditions and protein molecules can be modified during their synthesis, for example, posttranslation lipid modifications steps, or after their synthesis, for example, biochemical reactions with other molecules such as phosphorylation. As a consequence, the system is composed of a very large number of molecules with different functional properties. For example, the total number of protein molecules in a liver cell has been estimated to be about 7.9×10^9; so, if there are about 10 000 different gene products in a liver cell, each protein can have on average nearly one million molecules (Lodish *et al*., 2000). Understanding how these molecules are distributed, regulated, and how they interact with one another is a challenge.

Advances in biotechnology, such as rapid sequencing of entire genomes, and in information technology, such as large-scale web-based databases, have led to the discovery of a substantial number of previously unknown genes and their protein products in viruses, bacteria, archaea, and eukaryotes. Many large databases have been constructed to store and analyze genetic sequences and protein sequences and structures, such as the nucleotide database GenBank of National Center of Biotechnology Information (NCBI online, 2004), the protein database SwissProt at Geneva (SwissProt online, 2004), and Stanford Human Genome Center (SHGC online, 2004).

In addition to the large number of cellular components, interactions between the components occur through a variety of mechanisms. These interactions often directly represent the functions of components within the cell system. For example, gene transcription is controlled by different transcriptional regulators that initiate, terminate, inhibit, to regulate transcriptional processes by interacting with each other and with specific genetic sequences. The interactions between components integrate distinct cellular components into a central regulatory signal network as well as functional machines within the cell. Interactions between the regulatory network and the machines result in the observed systems behavior (Figure 1). A defining aspect of cellular systems is its regulatory topology based on component interactions. The regulatory topology of the cell represents the dynamic structure of the system and determines system behavior, therefore directly reflecting the functionality of cell. Because of its importance, regulatory topology continues to be the target of intense research. Such research usually focuses on identifying the regulatory subcelllular maps of specific or common cellular signaling processes, such as G protein-coupled signaling pathways (Neves *et al*., 2002). The microarray technology developed in recent years (Spellman *et al*., 1998; Iyer *et al*., 1999) has been successfully applied to the measurements of large-scale genetic regulatory networks (Davidson, 2002), and even protein interaction networks (Nielsen *et al*., 2003). Various computational approaches have been developed to analyze the structure of these complex biological networks, such as the clustering analysis to identify coexpressed genes in genetic regulatory networks (Eisen *et al*., 1998), the statistical analysis to study the connectivity of metabolic biochemical networks (Ravasz, 2002) and probabilistic models to infer regulatory cellular networks from disparate biological data (Friedman, 2004) and identification of regulatory motifs (Milo *et al*., 2002).

A significant challenge in understanding intracellular systems is how a complex cellular system containing thousands of components, in response to internal or external signals, performs the desired physiological functions accurately in spite of occasional component malfunction or noise from adjacent processes. In other words, what are the mechanisms by which individual cellular components are integrated into a coherent and functional system? Intuitively, a straightforward approach to this challenge is to define an exhaustive anatomy of the cellular system by listing every component and every interaction. This is a good starting point, but it is not sufficient. It is like trying to assemble a complex mechanical machine from a number of individual parts. Although we know exactly what function each part performs and which other parts it can be assembled with, we do not know how to put all the parts together to build a machine that is able to perform its designed functions accurately, effectively, and robustly. What we need in order to build a working machine from its parts and interactions list is the design principles of the machine. More explicitly, design principles describe how to build the machine with required functionalities from the functions of the individual parts and the interactions between those parts. For example, which parts should be assembled together? What is the state of each part to generate specific required functions? How is each part controlled? How do we protect key parts? How do we resist systems perturbations during function? What is the working range of machine within which each part functions in an error-free manner? How

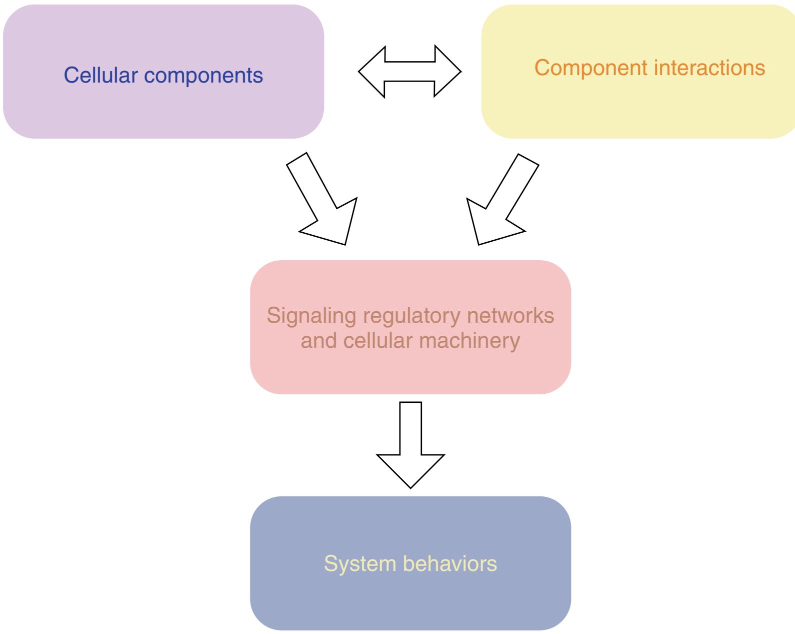

Figure 1 A schematic representation of a bottom-up approach to explain how systems level behavior is generated from components and interactions. The cell integrates cellular components and interactions into a functional systems by the means of regulatory signaling networks and cellular machines. Regulation of the functions of the cellular machines leads to the observed systems behavior

do we recover from error? A well-defined design diagram would provide answers to these questions. In understanding the design principles of cells, we can take advantage of natural selection processes. The cell has been going through billions of years of evolution during which only those cells with optimized systems and functions survived. To satisfy rigorous requirements for survival, it is necessary to have functionality coupled with accuracy and robustness. One way to approach this issue is to assume that survivors must follow similar design principles as human-made machines. Compared with engineering, systems biological research is a reverse process (*see* Article 110, **Reverse engineering gene regulatory networks**, Volume 6). Nature has designed a complex cell system, and the task of systems biologist is to study and understand how this system works and thus identify the overall the design principles. Because the cell is a complex but coherent functional system, the approaches to study this system have to be "systems aware", which means that we must analyze the cell from a systems perspective that can guide the design of experiments to explain the seemingly contradictory behavior of subsystems, search for hidden components, and predict unknown cellular behavior (*see* Article 107, **Integrative approaches to biology in the twenty-first century**, Volume 6). Such approaches are a major part of the emerging field of systems biology. This review covers two aspects of cell systems biology, dynamic machines, and design principles underlying the regulation of these machines.

2. Dynamic machines

The phenotypic behaviors of cells arise from the function of subcellular machines as the vesicle release machinery or the electrical response machinery of excitable cells that are located in a spatially restricted manner. Such machines exhibit two key features: tight spatially restricted control of these machines and dynamic stability. Local machine functions result from the dynamic control of cellular machines by the central signaling network to perform time- and space-dependent functions. Dynamic stability allows the machine to maintain its functionality within the context of the function of multiple cellular machines operating simultaneously.

It is essential that, within the cell, a variety of cellular processes are scheduled to perform required functions at appropriate times. Although the cell contains a large number of components, each cellular process uses only a fraction of total components, which means that only the components necessary for current process are active while others are quiescent or engaged in other functions. For signaling networks, different signaling pathways are activated at different times (Jordan *et al*., 2000), and for genetic networks, different gene expressions are turned on at different times (Davidson *et al*., 2002). These dynamic behaviors enable the cell to assemble and disassemble local machinery to perform the functions required for a specific process. This feature distinguishes cellular machinery from human-engineered systems whose structure cannot be changed on demand. There are two known mechanisms by which these dynamic features can be achieved. One mechanism is the transient formation of local cellular domains solely by the interactions between machinery components (e.g., the spatial patterns formed by signaling reactions) (Eldar *et al*., 2002). The other mechanism is the localization of machinery components at cellular compartments (e.g., plasma membrane, cytoplasm, and nucleus) (Weng *et al*., 1999) and cellular scaffolds (e.g., actin cytoskeleton) (Medalia *et al*., 2002).

Once assembled, the local machinery performs its designated function for the specific cellular process. Such functions result from the components and their interactions determined by the machine's regulatory topology. These local machineries can form higher-level cellular organelles such as the rough endoplasmic reticulum that contains both ribosomes and endoplasmic reticulum–bound posttranslational modifying enzymes required for the production of fully functional proteins. Therefore, the cell system can be always considered as a set of machines consisting of multiple components forming various levels of organization. The machines perform their functions by setting the components at preferred states through component interactions. These preferred states of components define the state of the whole machinery, and the state change of any components can affect the machinery state. For example, the fast growth of dendritic actin filaments is characterized by the high activities of machine components that regulate three processes: actin polymerization, actin depolymerization, and actin recycling. If the activity of any the components that regulates these processes changes, the overall growth rate will change (Pollard *et al*., 2000). Therefore, the dynamic behavior of cell system is governed by the state of the components that make up the cellular machines. Cells display both steady state and periodic dynamics. Steady dynamics is a status in which cellular machines operate at steady states, maintained by a constant level

of activity with the central regulatory signal networks. Steady state dynamics may be observed both in cells functioning at basal levels as well as in cells that have undergone activity-induced state changes such as neurons that display the long-term potentiation and long-term depression of synaptic responses (Sheng and Kim, 2002). Cellular machines can also operate at multiple steady states. For example, the mitogen-activated protein kinase (MAPK) signaling pathway that connects extracellular growth factor signals with nuclear transcriptional machinery exhibits bistable states dependent on the signaling stimulation by growth factors, and interestingly, this bistable behavior can be altered to monostable behavior by other signals (Bhalla *et al*., 2002). Periodic dynamics is perhaps one of the most important behaviors of biological systems such as the population model of predator and prey in ecology and the electric oscillation in neuronal and cardiac cells. Particularly, periodic dynamics exists in the biochemical signaling networks that regulate a variety of cellular processes such as glucose metabolism, calcium oscillation, pulsatile hormone signaling, and gene transcription (Goldbeter, 1996). A very common biological periodicity is the circadian phenomenon in which biological systems can adapt themselves to the 24-h periodic variations of environment (Dunlap, 1999). An early detailed molecular model for circadian rhythms was based on a set of five biochemical kinetic equations that described the oscillations of the period protein of Drosophila (Goldbeter, 1995). However, the periodic oscillations of cellular machinery can go out of control and become chaotic when oscillation dynamics is highly sensitive to the initial condition of the system (Goldbeter *et al*., 2001). Owing to the complex nature of periodic phenomena, computational approaches are valuable tools to analyze such systems (Goldbeter, 2002).

3. Design principles

With the large number of components and interactions, combined with the dynamics of local machinery, cellular system can exhibit many uncharacterized complex dynamic behaviors besides the steady and periodic dynamics described above. Since such complexity greatly complicates the in vivo observations of cellular dynamics, it becomes increasingly difficult to explain these observations through intuitive speculation or brute-force exhaustive mathematical modeling. Instead, systems biologists can try to deal with such complexity by applying the concepts of system control from engineering theory (Zhou *et al*., 1995).

3.1. Modular regulation

Despite its complexity, the cell is a biochemical machine constructed from molecules, so it must follow all the physiochemical rules of nature. In order to generate the required biological functions and maintain life, cellular machines need to manage the tremendously large number of components and their interactions in an efficient way. This efficiency requires cellular machines to organize their components into distinct modules, each of which is responsible for specific functions. To control these modules, a well-designed intermodular regulatory system is

present (Hartwell *et al*., 1999). Because modular regulation heavily determines the functionality of cellular machinery, many efforts, both experimentally and computationally, have been made to search for characteristic regulatory motifs that can explain various observations of the system. For example, autoregulatory motifs generate quick response to control input (Ren *et al*., 2000) and increase stabilility (McAdams and Arkin, 1997), chain regulatory motifs generate temporal sequential control (Simon *et al*., 2001), negative feedback motifs generate steady state dynamics (Buchman, 2002) and oscillatory dynamics (Goldbeter, 2002), positive feedback motifs generate bistability dynamics (Bhalla *et al*., 2002; Ferrell, 2002; Hasty *et al*., 2002), positive feedforward motifs generate quick response, large amplification, and high sensitivity to input signals (Goldbeter and Koshland, 1984; Lee *et al*., 2002; Shen-Orr *et al*., 2002), and multi-input motifs generate logical gate dynamics (Hasty *et al*., 2002). The design of these regulatory motifs for cellular machinery control share great similarities with engineering systems and highlight the physical origins of cellular systems.

3.2. Design of robust systems

Cells live in a world full of disturbances coming from environmental variation, intracellular and extracellular noise, and machinery malfunction. Systems within the cell must be able to maintain all the normal functionalities during these disturbances for the cell to survive, that is, the cell should display robust behavior. To achieve such robustness, cellular machines are designed with the following principles: (1) a relative intrinsic stability determined by the internal insensitivity of components themselves and their interactions to disturbance. Therefore, stability does not depend on machinery structure; (2) a dispersed regulatory structure that is determined by modular regulation. Both the physical and functional modularity of cellular machinery can prevent the malfunction or failure in one part of machinery from spreading to other parts and causing system-wide failures. Optimized modular regulatory structure can effectively stabilize the behavior of cellular machines against internal and external disturbances. For example, internal feedback regulation in the biochemical networks of bacterial chemotaxis makes the precise adaptation of bacteria to attractive chemical signals in environment very robust to the large variation of molecular concentrations and rate constants (Barkai and Leibler, 1997). Another example is the DNA robustness against damage by a feedback checking mechanism mediated by p53 protein. If DNA damage occurs, damage can be sensed by DNA-dependent protein kinases that can activate p53 protein. Active p53 protein then transactivates p21, which results in G1 arrest in cell cycle. This state is released when DNA is repaired. Thus, propagation of mutations due to DNA damage is limited. The design of cellular machines is a major mechanism for cellular machinery to attenuate intracellular noise to achieve various cellular functions (Rao *et al*., 2002); and (3) machinery redundancy, which introduces additional backups for important machinery components such that the failure of one component can be compensated by its substitution with another. Redundancy exists in both gene level and protein level. For example, at gene level, only about 256 out of 468 protein-coding genes are considered necessary and sufficient to sustain

the existence of *Mycoplasma genitalium* bacterium (Mushegian and Koonin, 1996) and, at the protein level, chemokine proteins are redundant in both their production and their function (Mantovani, 1999).

Unless individual cell systems are intrinsically stable in terms of their components and component interactions, system robustness is often achieved by including extra machines that can serve the same overall function. Thus, redundancies could be at the level of regulatory motifs or in actual machine itself. In either case, the overall goal is to offset the influence of disturbance on cellular systems and maintain functional stability within limits. When cell systems contain a large number of components and perform various functions, substantial increases in machinery structure is required to maintain the robustness of the large system. Thus, the maintenance of system robustness relies on an essential feature of cellular systems: system complexity. Cell systems are thought to be complex due to numerous cellular components, a large number of component interactions, and the emergent complex system behaviors (Weng *et al*., 1999). However, the complexity of a cell system can be concealed by its robust adaptation to a variety of internal and external disturbances until the emergence of unexpected changes and failures. This type of approach can be better understood by comparison with the design of complex engineered products such as the Boeing 777 airplane and the allometric scaling chart of optimal cruise speed (Csete and Doyle, 2002). The design principles of biological systems share great similarity with those of complex engineering systems in terms of two aspects of system design: the design of machinery function and the design of functional robustness. Both types of design can significantly increase the complexity of the system. This is illustrated by considering some examples. The design of complex biorhythmicity and its effects on the behavior of metabolic and genetic networks (Goldbeter *et al*., 2001), or the systems with extreme robustness, such as robust control of airplane flight (Yeh, 1998), reveal a paradoxical systems property. System robustness achieved by the increased complexity of system machinery comes at the cost of system fragility, which represents unanticipated system vulnerability to malfunctions and disturbances. To achieve robustness, extra regulation of machinery modules are added to the system. Robust metabolic networks usually have scale-free type of connections between network nodes (Ravasz *et al*., 2002). This feature makes metabolic networks more robust to random node failure than randomly connected networks, but more fragile to system-wide failures when hub nodes fail (Buchman, 2002). Thus, system robustness and fragility are two intrinsically linked system properties originating from system complexity. Well-designed systems have to make deliberate choices to balance between robustness and fragility to achieve an optimal function (Carlson and Doyle, 2002; Csete and Doyle, 2002).

3.3. Initiation of cell spreading: A case study in signaling network regulation of the actin-based cell motility machine

Motility is an important physiological phenomenon (*see* Article 114, **A complex systems approach to understand how cells control their shape and make cell fate decisions**, Volume 6). During development, the movement and migration of

cells is very important for the proper development of the embryo. The ability to move in response to extracellular signals is a critical property of hematopoietic cells and the mounting of immune responses. Cell movement involves the actin cytoskeletal machinery as well as the tubulin-based cytoskeleton. Sheetz and colleagues have recently developed quantitative approaches to imaging the spreading of mammalian fibroblasts when they come in contact with extracellular matrix proteins such as fibronectin (Dubin-Thaler *et al*., 2004). We have started to develop a computational process to model this process in terms of components and interactions.

A simplified connections map that can be used to represent the regulated prohypbreakcess is shown in Figure 2. This system is made up of a regulatory signaling network and the actin cytoskeletal machinery. The regulatory signaling network senses extracellular motility signals, for example, fibronectin in this case, by integrin receptors on cell membrane and transduces the signal to the interface layer between the signaling machinery and the actin machinery. The interface layer consists of several actin-binding proteins capable of regulating the process of actin polymerization and depolymerization. Each protein in the interface layer receives signals from the respective pathway of upstream signaling pathway and in response to these signals regulates the corresponding aspect of downstream actin machinery. Then, the actin cytoskeletal machinery reorganizes the structure of the actin cytoskeleton during polymerization and depolymerization reactions, which results in growth of actin filaments close to the plasma membrane. This growth of filament pushes the plasma membrane, generating force required for the cell to spread.

The dynamics of this motility machinery is well characterized by the multiphase model observed for the fibroblast cell spreading in the experimental setup. This model describes the motility behavior of the fibroblast cell before, upon, and after it contacts the fibronectin substrate on glass slide. Three phases are observed: (1) the basal phase in which spherical fibroblast cell demonstrates random local membrane protrusion before it contacts fibronectin substrate; (2) the transitional phase in which fibroblast cell explores the spatial distribution of fibronectin substrate by a few trial contacts and then decides whether or not to spread; and (3) the spreading phase in which spherical fibroblast cell spreads over fibronectin substrate to form a flat disk. This multiphase motility of fibroblast cell is realized by the cooperation of the multiple aspects of the dynamics of actin cytoskeletal machinery, each of which is regulated by the corresponding signaling pathway of upstream signaling regulatory machinery. This modular design ensures the effective control of complex dynamics of actin machinery by extracellular signals and intracellular signaling machinery. Moreover, this motility machinery is designed to be both sensitive to extracellular signals as well as have an intrinsically robust performance capability. This complex behavior can be seen in the multiple phases involved in fibroblast spreading (Dubin-Thaler *et al*., 2004). The time needed for fibroblast cell to explore extracellular fibronectin in the transitional phase is dependent on the distribution concentration of fibronectin on glass slide: the larger this concentration is, the lesser is the time needed in this phase. This sensitivity enables fibroblast cell to move toward more concentrated extracellular signals. Thus, the trigger to move is directly controlled by extracellular signals. However, when fibroblast cell enters the spreading phase,

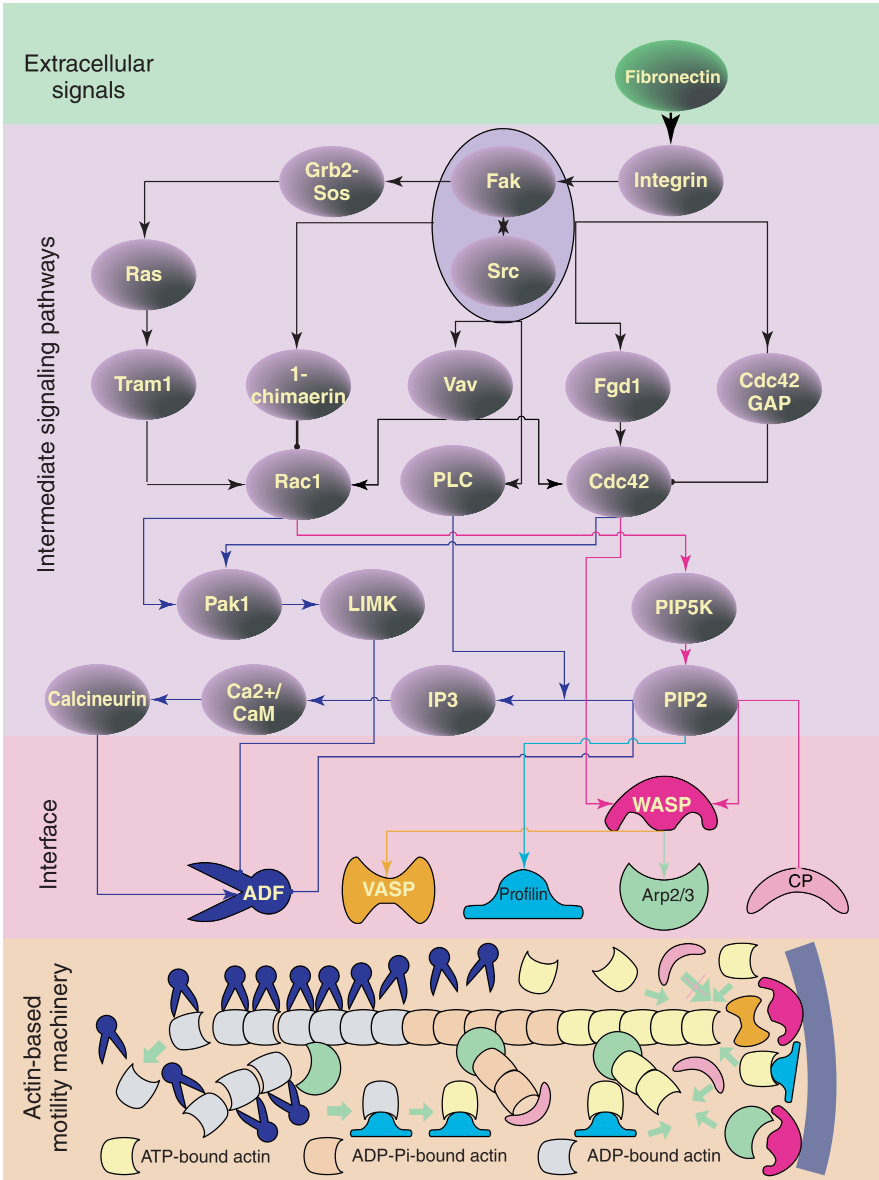

Figure 2 A cellular motility system consisting of the regulatory signaling network and the actin-based motility machine. The biochemical components of actin-based and integrin-regulated motility of fibroblast cell is shown as a connections map. The system can be thought to consist of four layers: (1) the extracellular signals, here the extracellular motility protein fibronectin that induce fibroblast cell motility is shown. There are other extracellular signals such as growth factors and chemotactic peptides that can affect this process; (2) the layer of intermediate signaling pathways that interact to form a network, that contains the integrin receptor, GTPases, tyrosine, and Serine-Threonine kinases; (3) the interface layer formed by several actin-binding proteins, which receive signals from the intermediate signaling pathways and in response to these signals regulate the downstream actin cytoskeletal machine; and (4) the layer of actin-based motility machinery, consisting of actin filaments and monomers that by polymerization, branching, and depolymerization generates cell motility. This is a simplified connection map in which only key components are shown

spreading rate is independent of fibronectin concentration. This behavior suggests that once spreading is initiated, the spreading of fibroblast cell mainly depends on intracellular signaling regulation and control of the actin motility machinery and is insensitive to extracellular signal. Thus, the system exhibits a robust functional response above a threshold level of an extracellular signal.

4. Conclusions

Although the cell is a complex system, its overall design favors functional modularity and robustness. Functional modularity is achieved by an array of cellular machines that can operate in a coordinated fashion. These machines are highly regulated and a central signaling network coordinates the regulation in response to extracellular and intracellular signals. In order to achieve overall robustness, the system has developed extensive redundancies at both the level of regulation as well as functional machines. The inclusion of these redundant subsystems results in a highly complex system. The high complexity of cellular regulatory networks and machinery unavoidably brings fragility into the system. Successful survival represents the ability to achieve balance between the robust and fragile properties of the system through functional modularity.

Specialist Review

Analyzing and reconstructing gene regulatory networks

J. Jeremy Rice, Aaron Kershenbaum and Gustavo Stolovitzky

IBM T.J. Watson Research Center, Yorktown Heights, NY, USA

1. Introduction

The study of networks is becoming an increasingly important area of biological research. A fundamental goal in the postgenomic era is to understand cellular function in terms of complex behaviors emerging from simpler interactions at the biomolecular level. Networks offer a natural representation for aggregating biomolecular interactions for a wide range of tasks including protein–protein interaction maps, pathway diagrams and in silico based simulations. Current gene regulatory networks are reconstructed by combining data from many experiments and multiple labs using hypothesis-driven approaches, but there is a growing effort to infer biological networks from high-throughput and genome-wide data sets. This chapter discusses topological properties of gene regulatory networks, and the methods to reconstruct these networks from high-throughput data.

2. Principles in network design

Networks arise in diverse areas including telecommunications, electric grids, social interactions, and many areas of biology (for review, see Strogatz, 2001). The entire field of network analysis is beyond the scope of this work; however, some general network design principles can be considered when analyzing biological networks. We mention some the most pertinent examples here:

Shared resources: Sharing resources is often beneficial, especially in the presence of economies of scale.

Cascaded functions: Networks may be used to perform sequential sets of operations or processes that can be organized as modules that are small subnetworks.

Control and stability: Networks may exist to provide control mechanisms for an otherwise uncontrolled set of processes.

3. Defining network properties

Figure 1 shows several examples of networks. Figure 1(a) illustrates a specific topology known as the Erdös–Rényi (E-R) network in which edges are randomly placed between nodes with equal probability (Erdös and Rényi, 1959). In this example, the graph is mostly disconnected so that no path exists between most pairs of nodes. One of the earliest theorems in random graph theory from Erdös and Rényi relates the number of edges in an undirected graph to the connectedness. The theorem states that the probability of the network being connected rises from 0 to 1 over the interval $N\log N - cN < E < N\log N + cN$, where N is the number of nodes, E is the number of edges, and c is a constant. Hence, these networks make a relatively quick transition from disconnected to connected as the number of edges approaches $N\log N$. This example is a directed graph that is typical for a gene regulatory network in which nodes represent genes and edges represent genes influencing other genes. We can define an indegree (outdegree) as the number of edges going into (out of) each node. For example, the node with vertical crosshatches has an indegree of 1 and an outdegree of 1, whereas the node with horizontal crosshatches has an indegree of 0 and an outdegree of 1.

Several network properties are now defined. The network in Figure 1(a) is considered sparse because the number of edges is $O(N)$ rather than $O(N^2)$ (i.e., only 16 edges out of 484 possible connections). For a directed graph with N nodes, there are N^2 possible connections if a node can connect to any other node including itself. Sparseness has been observed for many biological networks (e.g., see Yeung *et al*., 2002); however, the E-R graph in Figure 1(a) differs from real gene regulatory networks in many other respects. The connectedness of a graph describes the degree to which paths exist between the nodes that comprise the network. Figure 1(b) shows several networks that are connected, but with different properties. Network 1, called a clique, is considered cohesive because all nodes connect directly with all others. Here undirected edges are shown, but the properties are similar for directed edges. Network 2 is also connected but is not as cohesive because only the center node connects directly with the others. Network 3 illustrates the scale-free property that is defined by the distribution of node degrees following an approximate power law relation (i.e., $P(k) \approx k^{-\gamma}$). Many biological networks are scale-free (Jeong *et al*., 2001; Ravasz *et al*., 2002) with few high-degree nodes connected to many lower-degree nodes. In contrast, an E-R graph has a nodal degree distribution that is Poisson (i.e., the probability of a node having degree k is $P(k) \approx \mathrm{e}^{-d} d^k/k!$, where d is the average node degree).

Figure 1(c) illustrates a network that is both scale-free and small-world. Small-world refers to the property that any two nodes are connected by a relatively small number of hops (transitions across edges), as reported from many biological networks (Ravasz *et al*., 2002). This property is quantified by the diameter which is the maximum distance between any pair of nodes in the network, where distance is defined here as the number of hops in the shortest path between a pair of nodes. In the example shown in Figure 1(c), the scale-free property is reflected by few nodes with high degrees called hubs connected to many nodes of low degree. The hubs are then joined by connections (dashed traces) so that the radius of the network remains small. Figure 1 shows other network architectures that do not show this

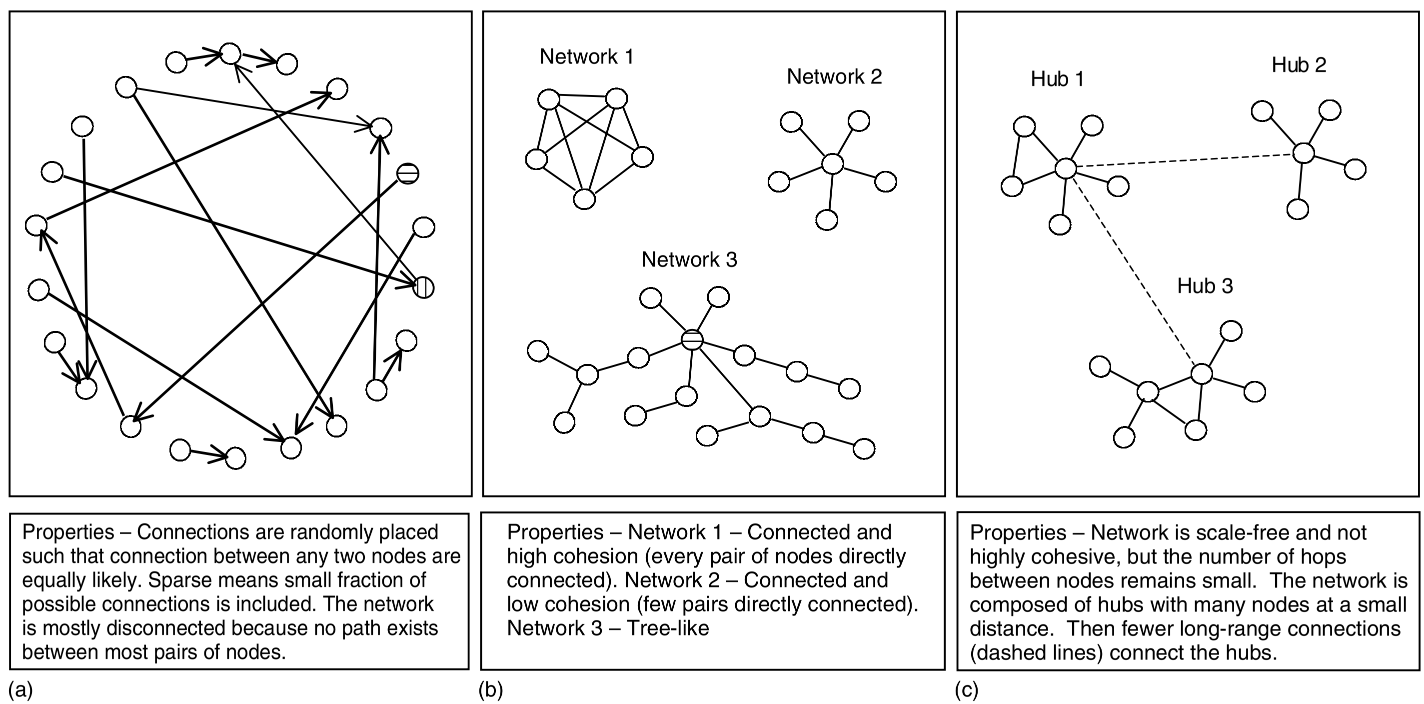

Figure 1 Sample networks illustrate network properties. (a) Erdös–Rényi (E-R) network; (b) three sample connected networks; and (c) scale-free and small-network is based on hubs with longer range links

scale-free property. For example, network 3 in Figure 1(b) is treelike with a root node. In these networks, the diameter grows as a function of the logarithm of the number of nodes.

4. Gene regulatory networks

Much of the previous discussion can be applied to a wide variety of networks. We now get more specific and consider gene regulatory networks in which connections represent the regulatory effect of one gene on another. For example, if gene A increases (or decreases) the expression of gene B, then an arrow with a positive (or negative) sign is placed from node A to node B. The actual mechanism is that gene A is transcribed and translated into a protein which in turn increases (or decreases) the rate of transcription of gene B. The expression of gene B can have further downstream actions on other genes or produce a protein that may have other effects (e.g., an enzyme could be produced to alter metabolic pathways (Reed *et al*., 2003) or repair DNA (Ronen *et al*., 2002)). Often, multiple genes can affect the target gene, and a gene may regulate itself, (*autoregulation*).

The transcriptional network from *Escherichia coli* is probably the most completely characterized gene regulatory network to date. Considerable knowledge of the regulatory mechanisms exists in the literature and has been condensed in databases such as Regulon DB (Salgado *et al*., 2000). In addition, considerable work has been done to analyze and reconstruct this network based on high-throughput data sources, as discussed later. By compiling the interactions in Regulon DB and other sources, networks similar to that shown in Figure 2(a) can be reconstructed (Shen-Orr *et al*., 2002). The network has 423 nodes and 578 connections. The representation does not show the autoregulation that exists in 59 of the 423 nodes. In addition, the regulatory network has three types of edges to represent activating (335), repressing (214), and both activating and repressing (29).

Several features of the network can be described using concepts already discussed. The network has a small number of nodes with high outdegree and a large number of nodes with only a single input or output connection to the rest of the network (see the starlike nodes in the center of Figure 2(a)). The node with the highest outdegree connects to 72 other nodes, and 15 other nodes have outdegree in the range of 10–26. The large number of nodes with high outdegree does not follow the Poisson distribution of E-R networks or the power law distributions of scale-free networks. Roughly, three-quarters of the nodes in the network (328 of 423) belong to a large connected component (here, a connection is assumed if any edge exists between a pair of nodes). The remaining nodes exist in components of 12 or fewer nodes. Figure 2(b) illustrates five distinct types of nodes in this network. External sources (red) and sinks (purple) are defined as having only one edge, either input or output, respectively. If one conceptualizes a flow of information from top to bottom, these nodes are starting and terminating points. Moving inward, external sources (yellow) and sinks (blue) connect to internal sources and sinks, respectively, that have two or more edges. The intermediary class (green) has relatively few nodes that connect only to internal sinks and sources (*see* Article 108, **Functional networks in mammalian cells**, Volume 6 and Article 113, **Metabolic dynamics in**

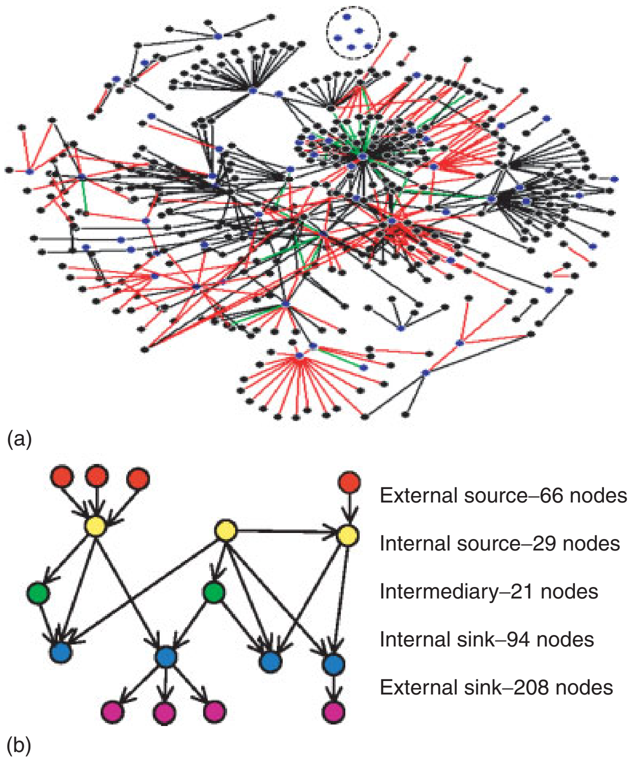

Figure 2 The transcriptional regulation network from *E. coli* (Adapted from Shen-Orr SS, Milo R, Mangan S and Alon U (2002) Network motifs in the transcriptional regulation network of Escherichia coli. *Nature Genetics*, **31**, 64–68 by permission of Nature Publishing Group). (a) The network has 423 nodes and 578 edges and is displayed using Pajek (Batagelj and Mrvar, 2003). The regulatory network has three types of edges to represent activating (black), repressing (red), and both activating and repressing (green) connections. The 59 nodes with autoregulation are shown in blue, and the others are shown in black. (b) All but the five isolated nodes (in the dashed circle) can be placed in five classes of nodes, as labeled, based on the number and types of edges (see text for details)

cells viewed as multilayered, distributed, mass-energy-information networks, Volume 6.

5. Motif-based analysis

The connectivity of networks is only one static aspect of the interactions in the cellular environment. Yet, the complexity contained at this level of description is already considerable. Sufficiently large networks have interesting large-scale properties, such as power law degree distributions and relatively small diameter. Another level of analysis seeks to identify local properties of the network such as motifs. A motif is a recurring, possibly inexact, pattern in the network that may represent a reused module within the gene regulatory network. Moreover,

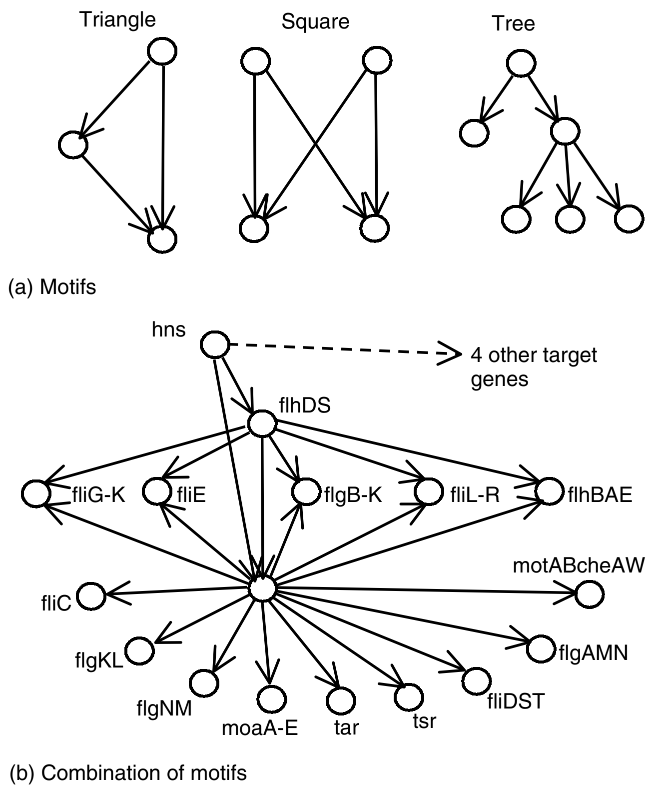

Figure 3 Samples of motifs discovered in the transcriptional regulation network from *E. coli* in Figure 2. Simple motifs in (a) can be combined in larger structures such as the example in (b) that corresponds to regulatory modules to assemble the flagella (see text for details)

the number of occurrences of motifs is usually compared to what is expected by chance, that is, the number discovered in randomized networks of similar properties (e.g., networks with randomized connections that preserve the in- and outdegree of each node). With this kind of analysis, motifs such as those shown in Figure 3(a) are found (Shen-Orr *et al*., 2002; Milo *et al*., 2002; Kershenbaum *et al*., 2003). The feed-forward triangle and the squares (also called bifan (Milo *et al*., 2002)) occurred at roughly two and three times the rate, respectively, as for the randomized network (Z-scores equal 4.9 and 7.5, respectively, Kershenbaum *et al*., 2003). The two examples are simple motifs that can be rigidly defined; however, motifs with more flexible structures can also be discovered. The descendent tree is a source node with several children, perhaps spread across levels (a two-level descendent tree is called a single input module in Shen-Orr *et al*., 2002).

One might also analyze networks as a composition of simple motifs. For example, the composite of motifs in Figure 3(b) is a composition of a descendent tree and several feed-forward triangles (Kershenbaum *et al*., 2003). The genes in this subnetwork are mostly associated with regulating the sequence and timing of proteins required to assemble the flagella (Kalir *et al*., 2001) (compare Figure 3(b)

with Figure 1 in the previous reference). Interestingly, the ancestor in this motif is a gene called H–NS, a master regulator in maintaining bacterial homeostasis under rapidly changing environments (Schroder and Wagner, 2002). Directly downstream of H–NS is flhDC, the master controller for the flagellar assembly process characterized in the previous work cited (Kalir *et al*., 2001). Note that the composite motif in Figure 3(b) was discovered on the basis of topology alone without regard to the name or function of the nodes. Hence, these results suggest that motif-based analyses can point to functional modules without full characterization of the nodes.

6. Biological interpretation of *E. coli* network topology

The layered network structure in Figure 2(b) suggests several properties. One can envision an "information flow" from a small number of sources (internal or external) to a much larger number of external sinks that can affect cellular processes. In the middle of the network, intermediary nodes may act as information integrators that subsequently affect larger numbers of downstream events. The layered networks produce short paths, perhaps suggesting that short temporal delays are favored over additional information integration that might be achieved with more levels of processing. Moreover, the negative autoregulation that is present in over 40% of *E. coli* transcription factors is thought to decrease rise-times in gene expression and hence may also decrease delay (Rosenfeld *et al*., 2002). Note that negative feedback loops at the level of gene regulation are not found, suggesting that additional stability as provided by this mechanism is not favored. Open loop control typically has better temporal responses and may be sufficient in this case. For example, the fast rate of division and high rate of error in DNA replication are thought to allow *E. coli* to rapidly "adjust parameters" in the metabolic pathways to make optimal use of the nutrients available in the current medium (Rosenfeld *et al*., 2002). Hence, this case suggests there is a regulation at the population level instead of at the level the individual gene network in this organism.

7. Reconstruction of pathways from high-throughput data

The *E. coli* network considered so far is constructed as compilations of data collected from the literature and other sources. Hence, the network represents a considerable part of the existing knowledge about the system and summarizes much of the underlying biology even though the functions of some genes may be better characterized than others. As mentioned earlier, however, *E. coli* is a special case in that it has been the object of a sustained research effort as one of the preferred model organisms for understanding prokaryotic biology. However, the knowledge base is sparser for most higher organisms. To address these limitations, considerable effort is being made to reconstruct networks based on high-throughput data and genome-wide data (*see* Article 110, **Reverse engineering gene regulatory networks**, Volume 6 and Article 118, **Data collection and analysis in systems biology**, Volume 6). However, high-throughput data is no panacea, and initial attempts to reconstruct large-scale, full kinetic models of the cell have faced

serious difficulties (Rice and Stolovitzky, 2004). From a theoretical perspective, the underdetermined nature of the problem (more unknowns than equations) implies that a unique solution is not generally possible because an infinite number of reconstructed systems are consistent with any given set of data. To deal with this nonuniqueness, the solution space is often limited by a priori, and often reasonable, assumptions such as linearity and sparseness, but even then the limitations of existing data render these approaches as mostly theoretical exercises except for reasonably small systems with high-quality data (Gardner *et al*., 2003; *see also* Article 110, **Reverse engineering gene regulatory networks**, Volume 6).

Another line of research seeks a reconstruction of the connectivity without full kinetic detail. We shall mention several efforts that are characteristic of the challenges facing the field (for a comprehensive review, see van Someren *et al*., 2002). A common approach is Bayesian inference methods as first used by Friedman *et al*. (2000) to analyze gene expression data. While these methods can handle noisy and incomplete data, the initial results showed that even three-node networks were hard to reconstruct in the yeast galactose metabolic pathway (Hartemink *et al*., 2001); however, much of the trouble may lie in the quality of the experimental data and not the method per se. Later work by the same group showed better results using synthetic gene networks where the researchers had better control of the data quality and quantity (Smith *et al*., 2003). In an elegant work (Gardner *et al*., 2003), researchers were able to reconstruct much of a nine-gene subnetwork in a DNA repair pathway in *E. coli* by controlled perturbations of a subset of the member genes. This work made the assumption of sparseness of the pathway connections and included a robust experimental design that kept low levels of noise in the real-time PCR measurement of transcript levels. In other recent studies (Segal *et al*., 2003; Troyanskaya *et al*., 2003), genome-wide yeast expression data and preliminary clustering were used to determine likely functional modules, that is, the sets of genes working together to perform a particular function. In addition, other data sources (candidate regulatory genes (Segal *et al*., 2003) and yeast two-hybrid data (Troyanskaya *et al*., 2003)) were combined to predict the functional modules. Hence, better results are found for understanding the regulation of sets of genes (versus single genes in initial attempts), more and perhaps better-quality data, and the use of complementary data types in addition to expression data alone.

8. Reconstruction of biological networks with pair-wise conditional correlation with a perturbed gene

We have proposed an alternative reconstruction method that seeks to determine the network connectivity only without generating a predictive model of the system (Rice *et al*., 2004). Starting with topologies based on the network in Figure 2(a), the network is endowed with dynamic behavior based on the work of Yeung *et al*. (2002). We propose an experimental design in which a single node is perturbed and the resulting effect on the rest of the network is measured. By computing the Pearson correlation of the expression profile of the perturbed gene to all the other genes in the network, the functionally connected genes can be inferred when the

correlation is above a set threshold. The process is repeated in a gene-by-gene fashion in order the reconstruct as large a network as needed. With this method, the network can be reconstructed with a high degree of accuracy that produces a reasonably low normalized fraction of false-positives and false-negatives.

The low reconstruction error rates of this and other similar studies are encouraging enough that full-scale automated reconstructions of gene regulatory networks may be possible in the foreseeable future with genome-wide data sets. False connections may be problematic for large network reconstruction (e.g., the *E. coli* 423 node network has $\sim 423^2$ possible connections so that a 1% false-positive error translates into more that 1000 false-positives, twice as many as the number of real connections). Therefore, reconstruction methods should usually be complemented with false-positive reducing approaches. Specifically, an optimal threshold to reject connections can be determined by modeling the distribution of correlation values of separate components representing connected versus disconnected nodes (Rice *et al*., 2004). Additional heuristics were developed to distinguish directly connected genes from indirectly connected genes that may also show high correlations (i.e., $X \rightarrow Z$ is distinguished from $X \rightarrow Y \rightarrow Z$).

While a large sparse network may make false-positives problematic, experimental noise may increase the rate of false-negatives. Other aspects of the *E. coli* gene regulatory network facilitated reconstruction. Specifically, the network hierarchical shape with large descendent trees that link relatively few sources to many sinks appears of be a topology that favors reconstruction. Specifically, the case of a gene being regulated by only one other (such as external sinks) is easier to reconstruct because the input and output show high correlation. In contrast, the infrequent structure of many nodes impinging on a single node is more difficult to reconstruct as the output is a function of many inputs and hence shows weaker correlation. Indeed, methods have shown similar difference in reconstruction accuracy for the case of single versus many inputs to a node (Smith *et al*., 2003). This latter study has shown difficulty with feedback pathways, but these are not seen to exist in the currently known *E. coli* network in Figure 2(a).

9. Toward a theory of biological systems

While allowing an unprecedented view into complex biological systems, the recent explosion of information has also opened a "Pandora's box". The systems biologist is like Newton under the tree who is pondering the apple in his hand. Fortunately, Newton connects the dots between the apple, the Earth, and his headache and develops calculus as the analytical tool to both understand and predict all motions, terrestrial and otherwise. A similar grand challenge for the systems biologist is to create a framework that allows the biologist to unify existing knowledge, to compare biological systems across species, and to make quantitative predictions of experimental manipulations. Network approaches are emerging as important ingredients in this quest. Networks are natural tools for compiling and mining high-throughput, genome-wide datasets. Networks are also tools to aggregate simpler interactions into large systems with complex behaviors. At the intersections of these tasks, large datasets can be used to infer network connectivity, pathways, and

potentially the kinetics between the interacting cellular players. Going the other direction, network-based tools such as motif discovery may help to decompose large systems into modules to more easily deduce functional relations. Clearly, networks will play important roles as the systems biologist tries to reign in the complexity and put the lid back on Pandora's box.

Specialist Review

Reverse engineering gene regulatory networks

Michael J. Thompson, Michael E. Driscoll, Timothy S. Gardner and James J. Collins
Boston University, Boston, MA, USA

1. Introduction

Cellular function arises from the interaction of thousands of distinct chemical components, including DNA, RNAs, proteins, and small molecules. Determining the networks of interactions between such molecules has become a major interest of the biological community, with the mapping of chemical interactions underway in many model organisms. This effort involves the consolidation of data from focused biochemical, molecular biology, and genetics studies (Bhalla and Iyengar, 1999; Davidson *et al*., 2002), with data from high-throughput, systematic approaches. Here, we discuss approaches for building network models from biological data, a task referred to as *network inference* or *reverse engineering* (*see* Article 109, **Analyzing and reconstructing gene regulatory networks**, Volume 6 and Article 60, **Extracting networks from expression data**, Volume 7) (D'haeseleer *et al*., 2000; Banerjee and Zhang, 2002; Brazhnik *et al*., 2002; de Jong, 2002; Wyrick and Young, 2002; Li and Wang, 2003; Stark *et al*., 2003a,b; Friedman, 2004; Herrgård *et al*., 2004; Rice and Stolovitzky, 2004; Taverner *et al*., 2004).

Network inference approaches can be categorized (Table 1) by the level of physical detail in the model, the biological data used to construct the model, the inference method or underlying mathematical structure, and the type of biological insight desired from the model. There is no direct correspondence between the features in these different categories. For instance, different types of biological data and different model types can be used to infer a qualitative network model to describe cellular function. In the next sections, we will discuss the different levels of physical detail used in molecular network models and the types of biological data that are available for network inference. We will then describe four recent studies in detail (Beer and Tavazoie, 2004; Liao *et al*., 2003; Ronen *et al*., 2002; Gardner *et al*., 2003) to present different strategies for inferring gene regulatory networks. These four studies are notable in their emphasis on gaining biological insight, and each uses a different type of biological data to accomplish the inference task. We will also discuss the novel advances and limitations of each approach. In

Table 1 Distinguishing between network modeling approaches

Distinguishing characteristic	Examples
Level of description (Figure 1)	Topological, qualitative, and quantitative models
Data used to construct model	Physical and functional interactions sequence, physical interaction, and molecular abundance data; time-series and steady state perturbation experiments
Model type	Boolean, Bayesian, linear, and nonlinear models
Model purpose	Descriptive, interpretive, and predictive models

the final section, we will provide concluding remarks and suggest future directions for network inference studies.

2. Cellular network descriptions

There are different levels of detail (Rice and Stolovitzky, 2004) with which one can describe the structure of a molecular network (Table 1; Figure 1). Each level of description is appropriate for answering a different set of biological questions, and successful modeling involves a choice of detail appropriate for the question posed. In the first, and most simplified model (Figure 1a), the network is described as a set of homogenous components interacting through topological connections, indicating only which components interact. Models of this type have been used to compare the structure of molecular networks with other interaction networks, such as social networks made up of human components, and information networks consisting of website components. The potential biological insight from this work includes determining the universal principles responsible for the evolution, organization, and function of molecular networks (reviewed in Barabasi and Oltvai, 2004).

The second, and most predominant type of model (Figure 1b) includes additional details to describe the functional heterogeneity of the components and the nature of the interactions. These qualitative connections indicate properties such as the direction (causality) and sign (activating or inhibiting) of an interaction. This type of model is most prevalent because the function of a molecular network is often obvious based on its qualitative structure and biological intuition.

The third, and most detailed network model (Figure 1c) provides a quantitative description of the interactions between network components, indicating how each component behaves as a function of its inputs. This level of detail is required to predict functions that are not conceptually intuitive, such as determining the mode of action of a pharmaceutical compound or simulating dynamic cellular behavior. With increasing model detail, the task of inferring the structure of a network becomes more challenging and requires more biological data.

The level of detail of network models can also differ by the amount of physical realism described by the model (Table 1). A network connection can represent the interaction of two components that physically interact, as in the case of

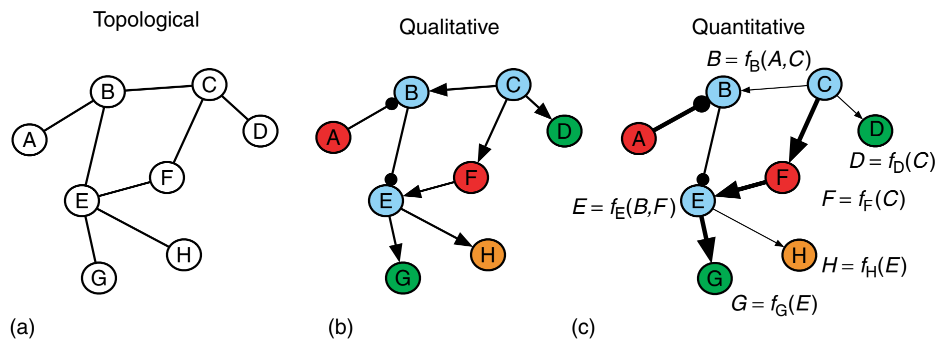

Figure 1 Molecular interaction network models can be described at different levels of detail. (a) Topological models describe graphs with homogenous molecular components and topological connections, indicating only which components interact. (b) Qualitative models include details of the functional heterogeneity of the molecular components (indicated by component color) and contain information on the direction (causality) and sign (activating or inhibiting) of interactions. Arrows begin at the causal factor and end at the component regulated by that factor. Arrow-tip terminated connections are activating; circle-tip connections are inhibiting. Component colors indicate different molecule functions; for instance, red components might be transcription factor proteins and blue components might be kinase proteins. (c) Quantitative models indicate how each component behaves as a function of the state of its inputs. For instance, component B will respond as a function of its inputs from components A and C. The strengths (indicated by line width of the arrow) of the interactions are captured in such a model

protein–protein interaction networks (Uetz *et al*., 2000; Ito *et al*., 2001; Gavin *et al*., 2002; Ho *et al*., 2002; Giot *et al*., 2003; Li *et al*., 2004), or it can simply represent a functional relationship between two components. For example, a functional connection between two genes in a gene regulatory network means that a change in abundance of the product (mRNA or protein) of one gene affects the abundance of the product of the other gene. The physical interactions that mediate such a connection are unknown or ignored for the purpose of a simplified model (Brazhnik *et al*., 2002). This review focuses on the modeling of gene regulatory networks, so all of the connections described are functional in nature.

3. Inferring gene networks from biological data

The achievable level of model detail and corresponding network inference strategy both depend on the type of biological data that is available. For example, data on the absolute or relative abundance of molecular species can provide a quantitative measure of the response of molecular networks to stimuli. This can enable topological, qualitative, or quantitative network inference, and is especially important for qualitative and quantitative models. Technologies such as gene expression microarrays (Schena *et al*., 1995; Lockhart *et al*., 1996), which monitor mRNA abundance, have made the systematic collection of such molecular abundance data accessible to individual laboratories.

The most common approach to gaining biological insight with systematically collected molecular abundance data is to cluster genes into groups with similar patterns of expression over a set of conditions or a time course following a

stimulus (Eisen *et al*., 1998; Wen *et al*., 1998; Alon *et al*., 1999; Tamayo *et al*., 1999; Holter *et al*., 2000). Coexpression clustering has been reviewed elsewhere (*see* Article 90, **Microarrays: an overview**, Volume 4) (Brazma and Vilo, 2000; D'haeseleer *et al*., 2000; Gerstein and Jansen, 2000; Lockhart and Winzeler, 2000; Quackenbush, 2001). Groups of genes that share expression patterns have been shown to function in similar cellular processes, and their protein products are more likely to participate in physical interactions with one another (Eisen *et al*., 1998; Ge *et al*., 2001; Jansen *et al*., 2002). Observing correlated expression for a set of genes is useful for the construction of a gene regulatory network because the coexpressed genes often have a similar set of regulatory inputs. However, correlation alone is insufficient to uncover the regulatory inputs and construct a model of causal gene–gene interactions. Such relationships can be identified using additional data types and/or methods that control the causal factor in the experimental design.

Data suitable for inference of causal gene relationships include DNA sequence data (Tavazoie *et al*., 1999; Bussemaker *et al*., 2001; Pilpel *et al*., 2001; Wang *et al*., 2002; Segal *et al*., 2003c; Beer and Tavazoie, 2004; Haverty *et al*., 2004), annotated lists of regulators (Ihmels *et al*., 2002; Segal *et al*., 2003a; Qian *et al*., 2003; Haverty *et al*., 2004), physical protein–DNA binding data (Bar-Joseph *et al*., 2003; Liao *et al*., 2003; Gao *et al*., 2004; Kao *et al*., 2004), time-series experiments (Arkin and Ross, 1995; Arkin *et al*., 1997; Holter *et al*., 2001; Ronen *et al*., 2002; Perrin *et al*., 2003; Sontag *et al*., 2004), and targeted steady state perturbation experiments (Kyoda *et al*., 2000; Ideker *et al*., 2001; Pe'er *et al*., 2001; Wagner, 2001; Bruggeman *et al*., 2002; de la Fuente *et al*., 2002; Kholodenko *et al*., 2002; Wagner, 2002; Wang *et al*., 2002; Yeung *et al*., 2002; Tegner *et al*., 2003; Gardner *et al*., 2003; Sontag *et al*., 2004; Vlad *et al*., 2004). Methods that use this data to uncover the causal relationships include Bayesian inference, signal decomposition, and parameter estimation, and will be described below.

In the remainder of this section, we will focus on four examples of how molecular network inference has been used to gain biological insight. Each of the four studies uses a different type of biological data to accomplish the network inference task. Our emphasis will be on the novel advances and limitations of each approach, and the lessons in network modeling that can be drawn in each case.

4. Inference from sequence data

A recent study by Beer and Tavazoie (2004) used systematically collected mRNA abundance data in conjunction with DNA sequence data to study the combinatorial regulatory program underlying gene expression (Figure 2). As described above, genes that have correlated expression patterns are likely regulated by one or more common transcription factor proteins. The response of a gene to the simultaneous binding of more than one transcription factor may not be a simple linear superposition of the responses to the individual factors (Davidson *et al*., 2002; Zeitlinger *et al*., 2003). Beer and Tavazoie (2004) hypothesized that in addition to the combination of transcription factors regulating a particular gene (incoming network connections), the binding location and orientation of these factors relative to each other and to the start of protein translation would influence

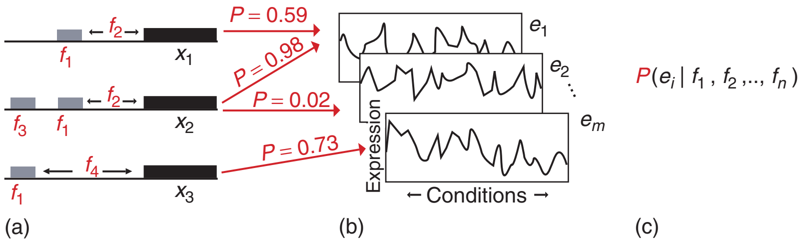

Figure 2 Approach taken by Beer and Tavazoie (2004) to determine quantitative connections between sequence determinants and gene expression. Red features are learned using the approach. (a) Sequence determinants of gene expression are enumerated as features, f_i, and include the presence of a motif, its orientation, and its distance from the translation start site. (b) Expression profiles, e_i, of genes under different conditions. The sequence determinants in (a) are mapped to corresponding gene expression profiles using a probabilistic function. (c) The conditional probability of a gene exhibiting a particular expression profile, e_i, based on sequence features, f_i, in its promoter. This probability is determined for all the expression profiles and sequence features using a Bayesian network

the expression of that gene. Information about the binding location and orientation of transcription factors is encoded in the DNA sequence, in which short patterns of nucleotides termed cis-regulatory motifs are recognized and bound by transcription factor proteins (Bulyk, 2003; Wasserman and Sandelin, 2004).

To accomplish their task, Beer and Tavazoie (2004) employed the Bayesian framework to describe the probabilistic dependencies between DNA sequence elements and gene expression profiles. First, they obtained data showing mRNA abundance changes in response to different environmental conditions, giving an expression profile for each gene. Next, they clustered the genes into sets of similar expression profiles, e_i (Figure 2b). They examined the promoter regions upstream of each gene, x_i, within a cluster of coexpressed genes for shared cis-regulatory motifs. Each motif was assigned a feature number, f_i, that could be used to indicate the presence (1) or absence (0) of that motif for a particular gene, x_i (Figure 2a). The motif orientation and distance from the translation start site were also assigned feature numbers. Finally, they described a Bayesian network (Pearl, 1988; Friedman *et al*., 2000; Pe'er *et al*., 2001; Perrin *et al*., 2003; Segal *et al*., 2003a,b,c; Friedman, 2004) mapping DNA sequence features ($f_1, f_2, \ldots, f_n$), to gene expression patterns (e_i) through the conditional probability, $P(e_i|f_1, f_2, \ldots, f_n)$, that a gene with a particular set of sequence features will participate in expression pattern i (Figure 2c). To train their model, Beer and Tavazoie (2004) searched through the space of sequence features to find a network (N) with the maximum probability of being correct given the observed data (D), using Baye's rule: $P(N|D) = P(N)P(D|N)/P(D)$. They withheld some data from the training set to test the predictive power of their model.

Beer and Tavazoie (2004) demonstrated their approach with gene expression data from the yeast *Saccharomyces cerevisiae*, responding to environmental stresses (Gasch *et al*., 2000) and a cell-cycle time course (Spellman *et al*., 1998). One expression profile they observed showed the stress-induced change in abundance of gene products involved in ribosomal RNA transcription and processing. They

identified two cis-regulatory motifs, termed PAC and RRPE (Sudarsanam *et al*., 2002), that are overrepresented in the promoter regions of these genes. Their Bayesian network model showed that the presence of the RRPE motif within 240 bp of the translation start site (ATG) of a gene indicates a 22% probability that the gene will exhibit the expression profile. Similarly, the presence of the PAC motif within 140 bp of the ATG indicates a 67% probability of the same. Importantly, the presence of both motifs within those respective locations is 100% indicative that the gene will exhibit the expression profile. Beer and Tavazoie (2004) describe this combinatorial program as AND logic, which strictly speaking means that the pattern is followed if both features are present and not followed if either individual feature or neither feature is present. Whether that same logical function would describe the response of a gene to the presence of activated versions of transcription factors that bind the PAC and RRPE motifs remains to be seen.

Beer and Tavazoie (2004) identified many other combinatorial sequence determinants of gene expression patterns in yeast, including some resembling OR and NOT logic functions. They demonstrated that those sequence features are predictive of the mRNA abundance changes of greater than 70% of the yeast genes responding to the observed environmental stress conditions. They also identified a program of combinatorial transcriptional regulation controlling the embryonic and larval development of the nematode *Caenorhabditis elegans*. They reasonably suggested that more and higher-quality expression data will enable the identification of many more regulatory programs.

The use of a Bayesian network approach provided some key benefits in this study. It allowed easy incorporation of heterogeneous determinants of gene expression, including not only sequence but also motif orientation and location. In addition, combinatorial gene regulation is commonly considered to involve a nonlinear response of gene expression to multiple simultaneous inputs. The Bayesian framework provides a probabilistic model with which these nonlinearities can be explored. Interestingly, it appears that regulation of genes by the PAC and RRPE motifs cannot be described using pure AND logic. For instance, genes containing only PAC or only RRPE can still exhibit the observed expression pattern (see above). Under these circumstances, which may be common in biological systems, it is likely that a linear model could also capture much of the important behavior. The additional benefit of using sequence data is that influential sequence determinants that are not associated with the binding of a particular protein, such as GC content affecting the physical properties of DNA, may influence transcription and could be learned using approaches similar to that of Beer and Tavazoie (2004).

Despite the excellent promise of this approach, some limitations should be considered in the future development of network inference strategies. For example, it is not yet clear how much of the information on the regulation of a gene is encoded in the DNA sequence in its promoter region. In higher organisms, the boundaries of promoter regions are less clear, and sequence determinants are commonly located tens of thousands of nucleotides upstream of a gene (Alberts, 2002). To infer a gene regulatory network model, one would also like to know the transcription factors that bind a given cis-regulatory motif. Coupling the approach of Beer and Tavazoie (2004) with genome-wide protein–DNA binding data determined using chromatin immunoprecipitation (Lee *et al*., 2002) is one

strategy to consider. Finally, as Beer and Tavazoie (2004) discuss, their statistical approach of averaging over genes that follow a common expression pattern may not enable the learning of very complex combinatorial regulation programs that have few or unique instances in a genome. However, the latter limitation may be partially overcome by using a strategy of comparing sequences of similar organisms (Bulyk, 2003; Cliften *et al*., 2003; Kellis *et al*., 2003; Wasserman and Sandelin, 2004).

5. Inference from physical interaction data

A recent study by Liao *et al*. (2003) demonstrated how mRNA abundance data and known qualitative network interactions from physical protein–DNA binding data (Ren *et al*., 2000; Lieb *et al*., 2001; Iyer *et al*., 2001; Lee *et al*., 2002; Kurdistani *et al*., 2002) can be used to determine quantitative gene regulatory network connections (Figure 3). Their approach also enabled the discovery of the activity profiles of a set of transcriptional regulators over a time course and a set of environmental conditions. The aim of their approach was to model the behavior of each of the regulated genes in the network as a linear combination of the activity profiles of the transcription factors that regulate that gene. The approach of Liao *et al*. (2003) is termed *network component analysis (NCA)*, and is suggested to yield more biologically relevant linear combinations than other signal decomposition approaches because of its use of prior information on regulatory relationships.

The network model includes a layer of transcription factors (Figure 3b) interacting with a larger set of regulated genes (Figure 3a). The NCA is provided

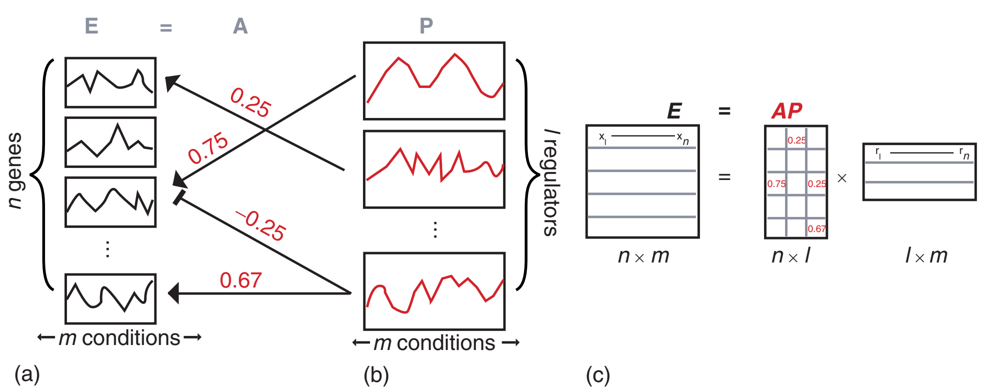

Figure 3 Approach taken by Liao *et al*. (2003) to determine quantitative gene regulatory connections and transcription factor activity (TFA) profiles using molecular abundance data and physical protein–DNA binding data. Red features are learned using the approach. (a) The algorithm is supplied with a matrix of experimental data, **E**, monitoring the abundance of n genes over m time points or environmental conditions. (b) The TFA profiles of the l transcription factors are contained in the **P** matrix. These TFA profiles are learned using the approach. The transcription factors direct regulatory connections, contained in matrix **A**, toward the genes in the network. The structure of these connections is known a priori, but the connection strengths and signs are learned using the approach. (c) The expression profiles, **E**, of the n regulated genes in the network are a linear combination of the l transcription factor activity profiles, **P**, weighted by the connectivity matrix, **A**

with a matrix, **E**, containing experimental data monitoring the abundance of each gene product in the network over a time course or set of conditions (Figure 3a). The approach by Liao *et al*. (2003) performs a linear decomposition of the expression data, **E**, into a connectivity matrix, **A**, and regulator profile matrix, **P** (Figure 3c). The connectivity matrix, **A**, describes the interactions directed from the transcription factors to the regulated genes. The **A** matrix is a pruned model of connectivity, representing a minimal nonoverlapping set of connections between transcription factors and regulated genes. Feedback connections are not allowed. The nonzero elements of matrix **A** are known from the physical protein–DNA binding studies, and the sign and magnitude (weights) of the elements (regulatory connections) are determined using NCA (Figure 3). The transcription factor activity (TFA) profile matrix, **P**, is determined using NCA, and describes the activity of the transcription factors (Figure 3b) over the same time course or conditions as the regulated genes. Decomposition of the expression data is achieved using a least-squares minimization, min $||\boldsymbol{E} - \boldsymbol{AP}||^2$, through an iterative procedure starting with the known network structure and random connectivity strengths.

Liao *et al*. (2003) demonstrated the NCA approach using mRNA abundance data taken over the time course of the yeast cell cycle (Spellman *et al*., 1998) and physical protein–DNA binding data obtained using systematic chromatin immunoprecipitation (Lee *et al*., 2002). They focused on 11 transcription factors known to regulate gene expression in a cell-cycle-dependent manner. To satisfy the criteria for NCA, the network of regulated genes was reduced to 441 genes under the control of these 11 factors and 22 other transcription factors, for a total of 33 regulators. Liao *et al*. (2003) used the NCA to determine the connectivity strengths and signs between these 33 transcription factors and the 441 genes, as well as the activity profiles of the transcription factors over the course of the cell cycle. Interestingly, they observed that the regulator activity profiles captured by the NCA do not necessarily correspond to the molecular abundance profiles of those regulators. They observed cases in which the activity profile of the regulator protein exhibited cyclical behavior, even though its corresponding mRNA abundance did not.

Even more compelling is a similar observation made by Liao and colleagues in a second study examining the response of *Escherichia coli* to carbon source transition (Kao *et al*., 2004). They decomposed the behavior of 100 genes responding to a shift from glucose to acetate growth media, into regulatory contributions by 16 transcription factors and the associated activity profiles of those regulators. One of the transcription factors they examined was CRP (combinatorial regulation programs), which requires the binding of the small molecule, cAMP, for its regulatory activity. Kao *et al*. (2004) showed that the activity profile (TFA) of the CRP-cAMP complex determined by the NCA algorithm matches the abundance profile of cAMP. With the NCA approach, it will be possible in principle to identify transcription factors whose abundance profile differs from their activity profile. These transcription factors would likely be regulated by means other than molecular abundance changes, including regulation by phosphorylation, localization, or complexation.

A limitation of this approach is the dependence on prior knowledge of the semiqualitative network connections. However, the construction of such network models is becoming more feasible with the use of DNA sequence data (described

above) and the determination of physical protein–DNA binding locations using chromatin immunoprecipitation.

6. Inference from time-series experiments

A recent study by Ronen *et al*. (2002) used time series of molecular abundance measurements to determine kinetic parameters (quantitative connections) for a network with previously known qualitative (direction and sign) connections (Figure 4). Their goal was to demonstrate the inference of a more complete descriptive model that could be used to predict the dynamics of the entire network on the basis of the observation of a single gene. The molecular network they examined was the DNA damage response and repair (SOS) pathway in *E. coli*. This network regulates the cellular response to DNA damage and involves more than 100 genes. Under normal conditions, the LexA transcriptional repressor ("R" in Figure 4b) blocks expression of other genes in the network. Under DNA damaging conditions, the RecA protein becomes activated and mediates LexA degradation, thereby relieving the repression of the SOS network genes.

Ronen *et al*. (2002) measured the temporal change in abundance (Figure 4a) of eight genes in the SOS network, including *lexA* and *recA*, following UV irradiation. They estimated the abundance of the proteins in the network using a fluorescent reporter protein placed under the control of the eight promoters. Their goal was to fit kinetic parameters for the production rate from each derepressed promoter (β_i), and the effective affinity of the LexA protein for each promoter (k_i), based on the time-dependent LexA repressor activity ($R(t)$; Figure 4b) and the observed promoter activity with respect to time ($X(t)$; Figure 4a). First, the LexA repressor activity ($R(t)$) was determined on the basis of singular value decomposition (SVD) from the different experiments. Next, the kinetic parameters were estimated using a Michaelis–Menten model for the regulatory dynamics (Figure 4c). This equation

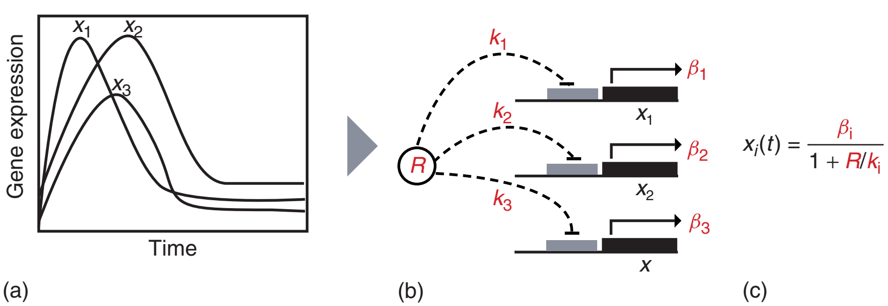

Figure 4 Approach taken by Ronen *et al*. (2002) to determine kinetic parameters (quantitative connections) for gene expression using time-series measurements of molecular abundance, and a prior model of the qualitative connections. Red features are learned using the approach. (a) Time-varying molecular abundances measured for every regulated species. (b) Regulatory interactions show that gene expression, x_i, is dependent on the repressor activity, R, the binding affinity for the repressor, k_i, and the expression level in the absence of repressor, β_i. (c) Michaelis–Menten model, showing the relationship between gene expression and the parameters in (b)

is specific to the system they investigated, and would take a different form if any of the genes were activated by LexA, or if LexA bound cooperatively to any of the promoters.

Ronen *et al*. (2002) were able to estimate kinetic parameters that reproduced the observed time-dependent upregulation of eight SOS network genes upon simulated LexA degradation. They discussed how the temporal order of the alleviation and reapplication of repression for the eight genes, as determined by the magnitude of the repressor binding affinity parameters, k_i, agrees with the order in which the genes function in the DNA repair process. Others have observed similar mechanistically significant temporal ordering of gene expression in different systems (Spellman *et al*., 1998; Laub *et al*., 2000; Kalir *et al*., 2001; Zaslaver *et al*., 2004), and this appears to be a key feature in transcriptional network dynamics. Ronen *et al*. (2002) also demonstrated how their kinetic model could be used to estimate the relative abundance of the active LexA regulator over the time course of the experiments, showing agreement with experiments that directly determined protein abundance (Sassanfar and Roberts, 1990). They also showed that the calculated error in estimated parameters could be used to anticipate additional regulation for a particular promoter that is not captured on the basis of LexA activity alone.

There are some limitations of this approach as a general solution for determining quantitative connections in gene regulatory networks. The strategy taken by Ronen *et al*. (2002) is specific for modeling the response of a group of genes to changes in activity of a single regulatory factor. The approach cannot describe the time-dependent response of a group of genes to multiple varying transcription inputs, or under circumstances in which there is feedback between the regulated genes and the regulatory factor. Elucidating the behavior in these more complicated regulatory system would require knowledge of the cis-regulatory logic describing multiple simultaneous inputs (Beer and Tavazoie, 2004). Another limitation of this approach is that it requires prior knowledge of the qualitative connections in the network, because the selection of an appropriate kinetic model will depend on the system structure. For the most part, the elucidation of such a qualitative network model remains a challenge. In principle, time-series data could be used to obtain the causality information required for inferring a network of qualitative connections with no prior structural information (Arkin and Ross, 1995; Arkin *et al*., 1997; Holter *et al*., 2001; Sontag *et al*., 2004). For example, Perrin *et al*. (2003) used the time-series data collected by Ronen *et al*. (2002) to infer a network of qualitative interactions between the eight genes in the SOS subnetwork.

7. Inference from perturbation experiments

A recent study by Gardner *et al*. (2003) demonstrated the use of molecular abundance data measured in response to targeted steady state perturbations to infer a gene network model with quantitative connections (Figure 5). The resulting network model describes the quantitative influence of each gene on the expression of every other gene in the network. One of the goals of the study was to use the resulting model to identify the major regulators in the network, which in their model need not

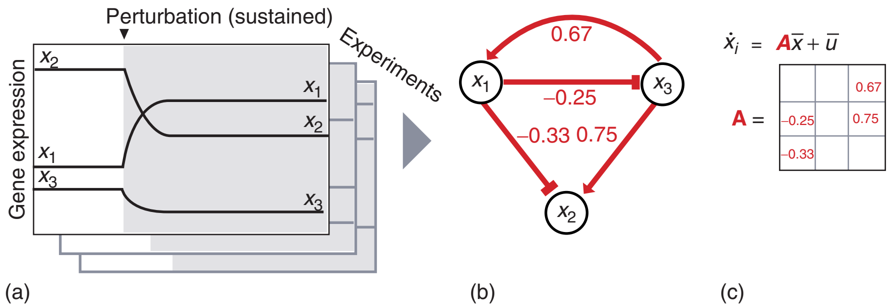

Figure 5 Approach taken by Gardner *et al*. (2003) to determine quantitative connections between genes on the basis of molecular abundance measurements following targeted steady state perturbations. No prior information on network structure was required. Red features are learned using the approach. (a) Steady state molecular abundance measured for every species following genetic perturbations. (b) Quantitative network model describes the influence of each gene on every other gene. The connectivity matrix, **A**, encodes these influence weights. (c) Linear model for the accumulation of each species, $\dot{x}_i$, based on the abundance of the other species, $\vec{x}$, the connectivity matrix, **A**, and the perturbations, $\vec{u}$. At steady state, the molecular abundances are not changing ($\dot{x}_i = 0$)

be transcription factor proteins. Another goal was to predict the targets of unknown perturbations (for instance, the molecular target of a pharmaceutical compound).

In the approach taken by Gardner *et al*. (2003), a cellular system near steady state is subjected to the specific perturbation (overexpression or downregulation) of a gene thought to have an influence on a network of interest. Once the system returns to steady state, the response of the system to the perturbation is measured by determining the molecular abundance of every species in the network (Figure 5a). Near a steady state, the behavior of the system can be approximated by a linear model (Figure 5c) describing the rate of accumulation, $\dot{x}_i$, of each species, i, in the network in terms of the abundance of every gene product in the network, $\vec{x}$, the quantitative connectivity matrix, **A**, and the perturbation, $\vec{u}$, made to the system. At steady state, the abundance of each species is not changing ($\dot{x}_i = 0$), so the equation in Figure 5(c) reduces to $A\vec{x} = -\vec{u}$. After making many perturbation-response measurements, the quantitative coefficients of A (Figure 5b), which represent the influence of each gene on every other gene, can be determined using linear regression.

Gardner *et al*. (2003) tested their approach, termed *network identification via multiple regression (NIR)*, on the SOS network in *E. coli* (described above). As a starting point, they applied the NIR method to a nine-gene subset at the core of the network. The authors used plasmid-borne copies of each gene to individually alter its abundance in nine separate experiments and measured the resulting changes in mRNA abundance for all nine components (Figure 5a). The NIR method was able to correctly identify 25 of the previously identified regulatory relationships between the nine genes, as well as 14 relationships that may be novel interactions or false positives. Moreover, the network model obtained by the NIR algorithm correctly identified the *recA* and *lexA* genes, the known principal regulators of the SOS response, as having the strongest influence (largest regulatory weights) on the

other genes in the network. Thus, the model can be used to identify which genes should be perturbed to elicit a maximal response from the network.

The network model obtained by the NIR algorithm was also used to identify the genes that mediate the network response to a particular stimulus. As illustrated in Figure 6, the network model correctly identifies the *recA* gene as the key mediator of the SOS network response to treatment with UV radiation, mitomycin C (MMC), and the quinolone antibiotic pefloxacin (each of which causes DNA damage). For novobiocin (Figure 6), a quinolone that does not cause DNA damage, *recA* is not predicted as the mediator of the expression response. The predictive power of the network model obtained using the NIR algorithm is due to its use of quantitative connections, and this level of model detail was specifically chosen to enable the identification of compound mode of action.

There are some limitations of the NIR approach for inferring molecular network structure and function. The predictive capability of the model was gained at the expense of its ability to describe many of the molecular interactions with mechanistic detail. For instance, while the NIR approach can include regulatory connections directed by nontranscription factors, the physical interactions that mediate those connections are often unknown, making it difficult to interpret the meaning of any particular connection. Other limitations of the approach include the challenge of delivering targeted (single gene) perturbations, and the difficulty in knowing which genes to perturb to most efficiently reconstruct the network model.

8. Concluding remarks and future directions

We have examined in detail four recent approaches to gene network inference (Beer and Tavazoie, 2004; Liao *et al*., 2003; Kao *et al*., 2004; Ronen *et al*., 2002; Gardner *et al*., 2003). These four approaches can be distinguished by several different model characteristics (Table 1). Despite differing in their underlying model structure, each of the four approaches provides a gene network model with some quantitative detail about the connections. For instance, the Bayesian network model of Beer and Tavazoie (2004) described the behavior of a cluster of genes as a probabilistic function of DNA sequence determinants, and the linear influence network model of Gardner *et al*. (2003) described the accumulation of one species as a weighted sum of the abundance of the other species in the network.

Although every gene regulatory network model has connections that represent functional relationships rather than physical interactions, the models can differ in their descriptive power. For instance, the approaches of Beer and Tavazoie (2004), Liao *et al*. (2003), and Ronen *et al*. (2002) describe connections between transcription factors (or the corresponding DNA sequence motifs to which they bind) and regulated genes. These interactions occur through well-understood mechanisms, and identifying such an interaction is therefore descriptive of the molecular behavior. The approach by Gardner *et al*. (2003), on the other hand, yields connections that are often mediated by several unknown physical interactions, making descriptive interpretation challenging. The resulting model, however, enables the prediction of behaviors resulting from the perturbation of nontranscription factors, including protein targets of pharmaceutical compounds.

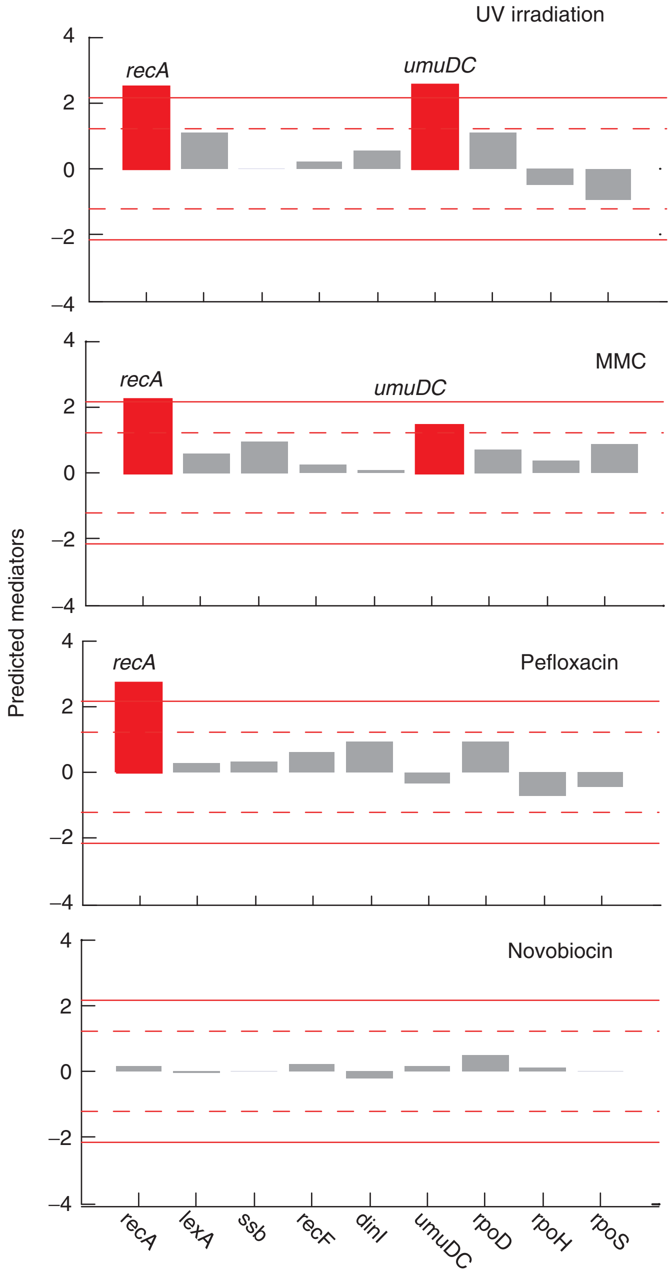

Figure 6 Prediction of genes mediating response to four different stimuli. The network model identified with the approach of Gardner *et al*. (2003) (Figure 5) was used to predict the mediators of expression responses following UV irradiation and treatment with three drug compounds. In the case of treatment with UV radiation, mitomycin C (MMC), and pefloxacin, all of which cause DNA damage, the *recA* gene is correctly predicted as the mediator of the expression response. For treatment with novobiocin, which does not damage DNA, *recA* is not predicted as the mediator of the expression response. Lines denote significance levels: $P = 0.3$ (dashed), $P = 0.1$ (solid)

The current trend in molecular network inference is in coupling different types of experimental data to improve the quality and completeness of the inferred model. The Bayesian formalism has been invoked in many studies as the most convenient approach for including previous knowledge and tolerating missing information (Beaumont and Rannala, 2004; Friedman, 2004). As Liao *et al*. (2003) and Kao *et al*. (2004) demonstrated, it is also possible to include prior information on network structure in linear models using a constraint-based approach (*see* Article 112, **Constraint-based modeling of metabolomic systems**, Volume 6). Another type of data that has not been discussed here are the synthetical lethal interactions, determined systematically in yeast by Tong *et al*. (2004). These interactions represent functional relationships between genes that are involved in similar or related cellular processes, and coupling these data with network inference approaches should prove fruitful. Finally, the use of physical protein–protein interaction data (Uetz *et al*., 2000; Ito *et al*., 2001; Gavin *et al*., 2002; Ho *et al*., 2002; Giot *et al*., 2003; Li *et al*., 2004) and metabolic network structure information (Covert *et al*., 2001, 2004) to trace the physical interaction pathways responsible for the functional relationships between genes will help elucidate gene network structure and extend the value of gene regulatory networks as descriptive models of cellular function.

Research into approaches for network inference would benefit from the availability of large, standardized sets of molecular abundance data collected with the goal of network inference in mind. As we have described in this study, time-series experiments and targeted steady state perturbation experiments will be particularly useful. The availability of such data in several model organisms (such as *E. coli*, *S. cerevisiae*, and *C. elegans*) would significantly advance biological discovery.

Specialist Review

Functional inference from probabilistic protein interaction networks

Joel S. Bader
Johns Hopkins University, Baltimore, MD, USA

1. Introduction

Access to complete genome sequence reveals how few genes have well-characterized function. A minority of genes in human and important model organisms have been classified according to the widely used Gene Ontology terms (Ashburner *et al*., 2000; Harris *et al*., 2004). The need to annotate gene function has driven the development of technologies for high-throughput experimental characterization of genes and proteins, both to generate raw data and to serve as the foundation for wider computational inference based on genome sequence.

Protein-coding genes are the most numerous class of annotated functional units in all sequenced genomics. The most direct characterization of a protein's function is to understand its physical interactions with other biomolecules: interactions with metabolites for enzymes, and interactions with other proteins and DNA for proteins that function in regulatory, signal transduction, structural, or other nonmetabolic processes. As the organism complexity increases, from bacteria to unicellular eukaryotes to metazoans, the fraction of proteins with nonmetabolic function also increases. These proteins' functions are best described by placing a protein in the context of a larger pathway defined by discrete protein–protein interactions. Two technologies, two-hybrid and mass spectrometry, have answered the challenge of probing protein–protein interaction networks at the full-proteome level.

Two-hybrid methods use an engineered system in yeast to test pairwise interactions between proteins from yeast or a foreign species. Large-scale protein interaction maps based on the two-hybrid method were generated originally for yeast (Uetz *et al*., 2000; Ito *et al*., 2001). Full-genome screens have now been reported for fly (Giot *et al*., 2003), and a screen for metazoan-specific proteins has been reported for worm (Li *et al*., 2004). Full-genome coverage in this context refers to an attempt to use each predicted protein-coding gene as input to the assay. Technical difficulties with the assays and undersampling combine to limit coverage to 5–10% of the total number of possible interactions. Coverage estimates remain imprecise.

Mass spectrometry methods use engineered proteins with affinity tags to permit immunoprecipitation of entire complexes whose protein components are then

characterized by mass spectrometry. This method has generated large-scale data sets for yeast (Gavin *et al*., 2002; Ho *et al*., 2002). Technical challenges have limited its use for more complex organisms. Other methods, particularly protein chips (Zhu *et al*., 2001), may rise to prominence in generating large-scale interaction data.

Admitted shortcomings of high-throughput proteomic screens are the 90–95% false-negative rates mentioned above, and also a high false-discovery rate (the fraction of reported interactions that are technological artifacts or not biologically relevant). These may arise from spurious or nonspecific interactions in the two-hybrid system or from high-abundance contaminants in mass spectrometry data. Joint analysis of multiple data sets, together with benchmark data from small-scale experiments and well-characterized complexes, suggests that 50% or more of the high-throughput interactions may be spurious (Deane *et al*., 2002; von Mering *et al*., 2002).

Confidence metrics that permit discrimination of true-positive and false-positive interactions have been crucial to the analysis of high-throughput proteomic data. The experimental groups generating high-throughput data have certainly been aware of this issue. Groups working on yeast (Ito *et al*., 2001) and worm (Li *et al*., 2004) use decision trees to classify interactions qualitatively as a highest-confidence core set and one or more lower-confidence categories. The fly group (Giot *et al*., 2003) developed a more sophisticated logistic regression model to generate a numerical score representing the probability that an interaction is biologically relevant. Training sets for this method were generated by cross-species network comparisons to avoid a possible bias from human experts. A similar model was then applied retrospectively to characterize published yeast interaction data (Bader *et al*., 2004). Protein complexes were represented by including all possible within-complex pairs, and a previous finding that bait–hit interactions are higher confidence than hit–hit interactions was reproduced (Bader and Hogue, 2002). Heterogeneous predictors, such as mRNA coexpression (Kemmeren *et al*., 2002), can be incorporated into such models. On-line databases of protein interactions are incorporating confidence measures in their data models (Xenarios *et al*., 2002; Bader *et al*., 2003).

Related methods, roughly equivalent to extrapolating statistical confidence models from observed to unobserved protein pairs, can be used to predict novel interactions. As with the experimental data, these methods report a quantitative probability or likelihood for each predicted interaction. Numerous computationally predicted interaction sets are now available (Goldberg and Roth, 2003; Jansen *et al*., 2003; Schlitt *et al*., 2003; Troyanskaya *et al*., 2003; von Mering *et al*., 2003; Fraser and Marcotte, 2004; Lehner and Fraser 2004).

An appealing computational model for protein network data is a weighted graph, where vertices represent proteins and weighted edges represent confidence levels for observed or predicted physical interactions. This type of model can incorporate information about characterized protein function by defining protein classes and attaching functional class labels to the corresponding vertices. The problem of protein functional inference maps to the classification problem of inferring labels for unlabeled vertices in the weighted network.

This review traces the evolution of network-based algorithms for protein function inference. Algorithms fall into three general classes: nearest-neighbor algorithms, which infer function on the basis of fixed or adaptive thresholds of neighbors,

including tree-building methods; energy minimization methods, which extend nearest-neighbor approaches by iteratively using expected class assignments to transfer annotations over longer distances; and computationally intensive Gibbs sampling that calculated label probabilities by averaging over a Monte Carlo trajectory. Where possible, comparisons of algorithm performance are included to analyze the trade-off between computational cost and predictive power. All the applications discussed below are to inference based on yeast protein interactions.

For some algorithms, a benefit of computational expense may be reduced sensitivity to choice of parameters, with a corresponding reduction in generalization error from highly tuned parameter sets. Algorithms that in principle yield exact answers to model problems but converge slowly do not necessarily perform better than simpler, faster methods based on approximate statistical distributions.

2. Nearest-neighbor algorithms

A nearest-neighbor algorithm satisfies the expectations of guilt-by-association: if an unlabeled protein interacts with proteins labeled primarily for a single class, it probably belongs to the same class. Schwikowski *et al*. (2000) used a nearest-neighbor algorithm based on a network of 2358 interactions among 1548 yeast proteins using 42 overlapping cellular role categories from the Yeast Protein Database. Neighbors were defined as all proteins within 1 interaction link, and the most frequent annotation in the neighbor list was assigned to unlabeled proteins. The accuracy of this method was reported as 72% versus 12% for a randomized network, with new predictions for 364 uncharacterized proteins. The authors detected significant cross-talk, or interactions between proteins belonging to different classes. While some cross-talk may be due to false-positive interactions, a certain amount of cross-talk is inherent due to real, transient interactions between well-defined protein complexes with related, but not identical, function. The cross-talk inherent in biological networks limits the predictive accuracy of methods based purely on nearest neighbors.

Work by Hishigaki *et al*. (2001) extended the nearest-neighbor approach to a greater number of links outward from a central protein. Protein classes were taken from the Yeast Protein Database, with 22 classes related to subcellular localization, 41 classes for biological process, and 57 classes for molecular function. The predictive accuracy of their method was 73%, 64%, and 53% for these three ontologies, respectively. Nearest-neighbor inference was based on the observed class frequencies within a distance of d links of a central protein. Class frequencies in the local neighborhood were converted to a χ^2 statistic based on the frequencies in the entire network, and the class with the highest value of χ^2 was assigned to the central protein. Use of χ^2, rather than raw frequency, was suggested to improve classification accuracy for low-abundance classes. The optimal radius d was determined by best performance for proteins with known classifications. The optimal radius for biological process and subcellular component was 1 link, with a clear degradation of performance for larger neighborhoods. Molecular function showed a slight performance increase from 1 to 2 links, but it is not clear that this increase is statistically significant. Together, these results suggest that

nearest-neighbor methods that do not consider edge weights are limited to ~70% accuracy. This study also introduces a recurring theme that protein interactions are more closely aligned with subcellular component and biological process than with molecular function.

Other measures of distance have been used to define neighborhoods. The PROTDISTIN algorithm of Brun *et al*. uses the Czekanovski–Dice–Sorenson (CDS) measure to calculate pairwise distances d_{ij}^{CD} between proteins,

$$d_{ij}^{\mathrm{CDS}} = \frac{\left|N_i \cup N_j\right| - \left|N_i \cap N_j\right|}{\left|N_i \cup N_j\right| + \left|N_i \cap N_j\right|} \tag{1}$$

where N_i denotes the set of proteins within 1 link of protein i (including i itself) and the absolute value notation indicates set cardinality (Brun *et al*., 2003). The BioNJ algorithm was used to generate a tree for 602 proteins based on the network distance (Gascuel, 1997). The PROTDISTIN algorithm then identifies maximal clades in which an absolute majority of classified proteins share a single class and transfers the class assignment to the other clade members. The distance threshold is clade-specific and hence adaptive. The method was applied to 2946 yeast protein interactions involving 2139 proteins from two-hybrid experiments, including proteins with at least three interactions and excluding highly connected proteins. Cross-talk was observed for interpenetrating clades, which arise from proteins belonging to multiple classes, and for smaller clades embedded in larger clades. The performance of PROTDISTIN was found to be superior to 1-link nearest-neighbor methods and more robust to noise in the input network data. A second tree-building method has been reported using the hypergeomtric distribution as a route to defining distances (Samanta and Liang, 2003). Following the calculation of the hypergeometric p-value for shared neighbors between each pair of proteins, the log of the p-value is used to drive distance-based clustering based on average linkage. While no direct comparison has been reported of these two tree-building methods, other work has shown that the hypergeometric p-value provides superior performance compared to other connectedness measures for inferring single links between proteins with shared interaction partners (Goldberg and Roth, 2003).

Bader's SEEDY algorithm extended the nearest-neighbor approach in two ways: first, edge weights improved the definition of a neighborhood; second, multiple sources permitted classification based on seed proteins of interest (Bader, 2003). The SEEDY method uses a breadth-first search on a weighted graph to identify a list of proteins ranked by their highest scoring path to a seed protein. Path weights are calculated by multiplying the confidence of each edge in the path, a number in the range 0–1. Algorithm performance was measured by selecting known protein complexes, using a subset of protein components as the seeds, and assessing the recall of other members by a receiver operating characteristic (ROC) curve. True-positives rates of 20–60% corresponded to false-discovery rates of 50–80%. Performance using the actual edge weights was demonstrated to improve upon performance with a permuted set of edge weights keeping the network topology fixed.

While the SEEDY method improves on earlier nearest-neighbor methods, it will eventually fail when high-confidence edges percolate the network. At the

percolation transition, virtually every protein will have an edge of confidence $\sim$1, and virtually every pair of proteins will be connected by a path of weight 1. The PRONET algorithm by Asthana *et al*. (2004) introduces probabilistic sampling into the neighborhood calculation. In the PRONET method, the weighted probability assigned to each edge defines a probability distribution on the space of all networks:

$$\Pr\left(\{e_{ij}\}\,\middle|\,\{p_{ij}\}\right) = \prod_{(ij)} p_{ij}^{e_{ij}} (1 - p_{ij})^{1-e_{ij}} \tag{2}$$

where $p_{ij} \in [0, 1]$ is the edge weight and $e_{ij} = 1/0$ denotes the presence/absence of an edge for each pair of proteins (ij). An ensemble of networks is sampled from this distribution, and pairs of proteins are ranked by frequency of co-occurrence in the same connected component. Trials with known complexes were used to optimize the edge weights and to determine an appropriate rank-based threshold for prediction. In practice, the probabilities $\{p_{ij}\}$ are rescaled by a single adjustable parameter $(1 - \alpha)$, where α is interpreted as an additional error rate for the probabilistic edges.

A further generalization of PRONET has been described by Huang *et al*. (2004) as a series of algorithms PROPATH-BIN, PROPATH-ALG, and PROPATH-EXP. The series of PROPATH algorithms use the same network probability space as PRONET. The PROPATH algorithms retain information that is discarded by PRONET, however: the number of links separating pairs of proteins that are located in the same connected component. The distances observed over the ensemble of sampled networks are combined into a single summary statistic. Note that the average distance is ill defined because proteins in separate connected components are at infinite distance. The PROPATH algorithms transform the distances prior to averaging: PROPATH-EXP takes the average of $\exp\left(-\lambda d_{ij}^{(k)}\right)$, and PROPATH-ALG takes the average of $\left(d_{ij}^{(k)}\right)^{-\lambda}$, where $d_{ij}^{(k)}$ is the shortest-path distance between protein pair (ij) in the kth sampled network, and λ is an adjustable parameter representing the inverse length scale of the network neighborhood. The PROPATH-BIN algorithm is the limit of PROPATH-EXP and PROPATH-ALG as $\lambda \to \infty$, which coincides with the PRONET algorithm.

Huang *et al*. performed a head-to-head test of the SEEDY, PRONET, and PROPATH algorithms to recover known protein complexes seeded by a subset of components. These tests led to two conclusions. First, for optimized parameters, all of the algorithms had roughly equivalent performance. This is significant because the SEEDY algorithm does not require sampling of probabilistic networks and is thus $\sim$100 $\times$ faster than the PRONET and PROPATH algorithms. Second, optimized parameters do not necessarily transfer across the methods. In particular, parameters optimized for SEEDY give strikingly poor performance with PRONET. The PROPATH-ALG and PROPATH-EXP methods showed the least sensitivity to parameterization. Results were not sensitive to the choice of the inverse length-scale λ, the choice of algebraic versus exponential decay, or the optimization of the adjustable error-rate parameter required by PRONET. The PROPATH-ALG and PROPATH-EXP algorithms have the same computational cost as PRONET, and

good performance over a range of parameters may provide increased protection against over-fitting and generalization error.

3. Energy minimization and generalized belief propagation

The 1-link nearest-neighbor method is isomorphic to the following energy minimization problem. Let $\{s_i\}$ represent the class assignments for proteins with known classes, and let $\{s_\alpha\}$ represent predicted classes for the remaining proteins. Let $e_{i\alpha} = 1/0$ represent the presence/absence of an interaction edge between proteins i and α. Define the potential energy U as

$$U\left(\{s_\alpha\}\,|\{s_i\}\right) = -\sum_{(i\alpha)} e_{i\alpha}\delta\left(s_i, s_\alpha\right) \tag{3}$$

where $\delta(s,s')$ is the discrete Kronecker delta function, 1 if $s = s'$ and 0 otherwise. The minimum energy is clearly obtained by selecting each s_α to maximize its agreement with its direct neighbors, which is identical to 1-link nearest-neighbor classification.

The energy function may be generalized by introducing terms corresponding all pairs of connected proteins, in particular, proteins without known classification:

$$U\left(\{s_\alpha\}\,|\{s_i\}\right) = -\sum_{(ij)} e_{ij}\delta\left(s_i, s_j\right) - \sum_{(i\alpha)} e_{i\alpha}\delta\left(s_i, s_\alpha\right) - \sum_{(\alpha\alpha')} e_{\alpha\alpha'}\delta\left(s_\alpha, s_{\alpha'}\right) \tag{4}$$

The sums are over distinct pairs of connected vertices, corresponding to a single contribution from each edge. The first sum has fixed value determined by interactions between proteins with prior classifications and is ignored. The second sum corresponds to the 1-link nearest-neighbor energy. The final sum reflects interactions between proteins with newly predicted classifications. This energy function corresponds to a frustrated spin system on a disordered lattice. Equivalently, it is termed a *Markov random field* because the state of each vertex depends only on the states of its immediate neighbors. Global energy minimization is intractable for such systems, and the lowest energy state may be degenerate. Nevertheless, methods such as simulated annealing (Kirkpatrick *et al*., 1983) that avoid the local minima identified by steepest descent methods can used to characterize low-energy states.

Vazquez *et al*. (2003) used simulated annealing with the energy function of equation (4) to predict protein function based on 424 classes Compared to the 1-link nearest-neighbor method, the energy minimization method has 5–10% greater classification accuracy and is more robust to random errors in the interaction network. In a subsequent comparison to the tree-building method, however, the energy minimization fared poorly: PROTDISTIN was able to predict accurate functions for 58% of recently characterized proteins, while energy minimization yielded accurate functions for only 31%. Although this comparison is preliminary, it seems unlikely that energy minimization as described by Vazquez *et al*. will outperform the much faster, deterministic tree-building approach. In related work, Karaoz *et al*. (2004) used local relaxation to quench to a local minimum in the

potential energy surface, with interaction edges corresponding to both protein interactions and associations inferred from mRNA co-expression.

Ignoring for the moment the distinction between classified and unclassified nodes, equation (4) becomes

$$U(\{s_i\}) = -\sum_{(ij)} e_{ij}\delta\left(s_i, s_j\right) - \sum_i h_i(s_i) \tag{5}$$

where $h_i(s_i)$ represents prior knowledge of the class s_i for protein i. An alternative to calculating the configuration $\{s_i\}$ that minimizes the potential energy is to calculate the probability of a configuration according to its Boltzmann weight,

$$\Pr(\{s_i\}) = \frac{\exp\left[-U(\{s_i\})\right]}{\sum_{\{s_i\}} \exp\left[-U(\{s_i\})\right]} \tag{6}$$

and then to obtain expectations for each label as the marginal sums,

$$\Pr(s_i) = \sum_{\{s'\}} \Pr\left(s_i, \{s'\}\right) \tag{7}$$

where $\{s'\}$ includes all labels other than s_i. These types of models gained prominence in image recognition (Geman and Geman, 1984). For acyclic networks, belief propagation provides an efficient shortcut to calculating the exact marginal distributions that is linear in the number of interactions. Belief propagation corresponds to calculating the label distribution that minimizes an approximation to the free energy that includes all 1-vertex and 2-vertex terms, termed the *Bethe approximation*, and can be considered loosely as a mean field theory for vertex pairs. These types of algorithms are not trustworthy for networks with loops because of slow or incorrect convergence. Kikuchi (1951) described higher-order free energy approximations based on larger clusters of vertices, which become exact as the cluster size becomes as large as the largest loop in a network. Yedidia *et al*. demonstrated the equivalence between message passing algorithms and free energy approximation, then showed how Kikuchi cluster expansions lead to generalized message passing algorithms that are readily applied to networks with loops (Yedidia *et al*., 2000; Yedidia *et al*., 2002). Mezard and Parisi (2001) developed similar approaches in the context of spin glasses.

Letovsky and Kasif (2003) recognized that instabilities with belief propagation can also be avoided by limiting the number of iterations to be smaller than the minimum loop size, which is three edges for an undirected graph. They implemented probability updates on the basis of a local Bayesian model for the classification of a protein based on its nearest neighbors, ran two iterations with probability updates for unclassified proteins, then set a threshold to fix the classification of a subset of unclassified proteins. The algorithm was then restarted and run exhaustively until no further labels changed for a network of 13,607 interactions between 4708 proteins. Each of 1951 GO terms was used in turn for classification. While no direct comparison was made with other methods for the

same network, the first probability propagation step should be roughly equivalent to a 2-link nearest-neighbor method. Furthermore, Letovsky and Kasif report that subsequent iterations resulted in ~50% additional unclassified proteins acquiring labels. Thus, this method is likely to have accuracy similar to nearest-neighbor methods but with significantly higher recall.

Leone and Pagnani (2005) instead implemented a full version of message passing at the Bethe approximation level. In careful comparisons on the same underlying network, they find that message passing far outperforms simulated annealing, which in turn outperforms nearest-neighbor methods. Leone and Pagnani incorporate a temperature parameter that is below the critical temperature, leading to stable predictions for class probabilities. Presumably, these probabilities represent Boltzmann-weighted sums over the same low-energy states that simulated annealing is designed to sample. The superior performance of message passing suggests that the simulated annealing method is inefficient in sampling the low-energy states. Thus, the computational efficiency of message passing in generating the exact probability distribution for an approximate free energy function provides an advantage over simulated annealing, which uses the exact free energy but is far slower to converge.

4. Gibbs samplers

An alternative to message passing, which rapidly calculates marginal probability distributions based on an approximate free energy function, is Gibbs sampling, which uses Markov chain Monte Carlo to generate a trajectory whose long-time average should yield exact marginal distributions. Convergence requires ergodicity; on the basis of the slow convergence of simulated annealing, ergodicity should not be assumed, even for thermal distributions.

Deng, Chen, Sun, and coworkers have used Gibbs sampling to perform functional inference based on protein interaction networks (Deng *et al*., 2003) and combined protein interaction/genetic interaction networks (Deng *et al*., 2004). Parameters for the conditional probabilities of the Gibbs sampler are estimated using label correlations for interacting proteins with known classes, which corresponds to a Markov random field and sets a natural temperature scale. While it would be interesting to know whether this temperature is above or below the critical temperature for the network, this aspect of the sampling is not discussed. Performance is superior to nearest-neighbor methods. Comparisons with simulated annealing and message passing methods, however, have not yet been made.

5. Summary and prospects

Performance criteria for functional inference algorithms include computational cost, statistical rigor, and predictive accuracy. Ideally, one would expect that all three criteria increase together, with a trade-off of higher computational cost for increasing rigor and accuracy. Perhaps surprisingly, this is not the case.

The fastest and least sophisticated algorithms, which transfer class predictions from nearest neighbors, indeed have the lowest accuracy. Recall is also limited because these algorithms do not transfer predictions across multiple unclassified proteins. Simple heuristics based on tree building, breadth first search with weighted edges, and sampling over probabilistic networks governed by edge weights, all provide substantial improvement. These algorithms can be interpreted as adapting the spatial range of neighbor sampling to account for network topology and confidence. The probabilistic sampling approaches have moderately increased computational cost, but are significantly less sensitive to precise optimization or tuning of edge weights. The PROPATH-ALG, PROPATH-EXP, and PROTDISTIN algorithms are likely the best of this class; comparisons of these algorithms have yet to be made.

More rigorous algorithms define a probability distribution for protein classes and attempt to predict classes based on this distribution. The form of the probability distribution is a Markov random field or spin lattice, in which the class of a protein depends only on the classes of its interaction partners. Despite the short-range potential energy function, connected series of links generate effective long-range correlations. Simulated annealing attempts to identify the ground state of an exact probability distribution that minimizes clashes between class labels of interacting proteins. It is computationally expensive, and actually performs worse than the much faster PROTDISTIN method. The poor performance is likely due to convergence and inadequate sampling of the relevant low energy states. Message passing belief propagation instead calculates exact marginal distributions for an approximate probability distribution. Message passing methods can be much faster to converge than simulated annealing, and also offer improved performance in reported comparisons. The statistical foundation of the free energy minimization problem underlying message passing offers a theoretical advantage over less rigorous nearest-neighbor methods.

Gibbs sampling methods use Markov chain Monte Carlo to calculate trajectories whose time averages for ergodic systems converge to the correct properties for the correct probability distribution function. Requiring lengthy trajectories and assuming ergodicity are the primary drawbacks of Gibbs sampling. The simulated annealing results on related potential surfaces suggest in particular that trajectories may not be ergodic.

Further improvement in protein functional inference should be realizable by combining features of the methods described. For example, the message passing methods have not incorporated edge weights for protein interactions. Edge weights fit naturally into the Markov random field/spin lattice formalism and have in fact been used to incorporate mRNA co-expression measurements into these models. Advances may also come from improved conceptual models. One limitation of all the models described here is the transitive assumption: if A interacts with B, and B interacts with C, then A and C are functionally linked. This assumption fails for transient connections between protein complexes (Han *et al*., 2004) and also for distinct complexes with a shared set of subunits. Explicit consideration of apparent cross-talk could simplify the protein complex prediction problem, thereby improving functional inference.

Specialist Review

Constraint-based modeling of metabolomic systems

Daniel A. Beard

Hong Qian
University of Washington, Seattle, WA, USA

1. Introduction

Since the time of Newton, a central dogma of scientific thinking has been that physical systems are best understood by representation in terms of the smallest possible subsystem (i.e., model) that captures the important mechanistic interactions. The influence of gravity in maintaining the earth's orbit about the sun is satisfactorily explained by analyzing the equations of motion representing a universe consisting of two massive bodies. Still, a complete mathematical analysis of the three-body problem remains out of reach, and most quantitative analyses of practical engineering problems, such as the analysis of the material properties of metal composites and the building of aircraft, are based on a combination of mechanistic models with intermediate-level empirical descriptions in quantitative terms. This approach is typical of engineering solutions to complex problems in physical sciences.

Living biological systems consist of not two, or even two hundred interacting components. Analysis, prediction, and rational manipulation of cellular function requires a mechanistic understanding of physical systems of unimaginable complexity. These are truly *complex systems*. Furthermore, each biological system is geared toward a unique function (or functions), a concept usually lacking in the physical sciences but central to engineering (Hopfield, 1994).

Two other disciplines that have tackled complexities similar to those encountered in Systems Biology are economics and ecology. It is arguable that mathematical thinking, language, and modeling are well-accepted components of these two fields. In addition, in both fields there is a clear distinction between the so-called micro- and macroscopic views. The microscopic view focuses on the small-scale mechanistic components of a system, while the macroscopic view treats the systems as a whole. As in biology, both economics and ecology have yet to establish a quantitative framework connecting the two viewpoints.

While it may seem natural to follow the path paved by Newton in constructing a differential equation–based representation for biological systems, we should not

treat uncritically the assumption that a useful representation of this form always exists. Popular mythology aside, Newton stood on no one's shoulders. Similarly, we do not require Systems Biology to stand on his alone.

Clearly, certain aspects of cellular physiology are successfully quantified via a traditional kinetic differential equation–based theory. A classical example is the electrophysiology of excitable cells, a field pioneered by Hodgkin and Huxley (1952). On the basis of their foundational description, models of ever-increasing complexity have been introduced, leading toward more complete computational models of cellular electrophysiology (Noble, 2004; *see also* Article 115, **Systems biology of the heart**, Volume 6). However, it is not immediately clear that differential equations will provide a universal framework for integrating these models with cellular mechanics, metabolism, genetics, and other phenomena. It seems more likely that no such universal mathematical framework will exist for Systems Biology.

In the past several decades, progress in cell biology has been driven mainly by the philosophies of and methodology from biochemistry and molecular genetics (Lazebnik, 2002). Biochemistry emphasizes individual reactions and their chemical nature: what are the reactants and products; which enzyme is involved; and what is the protein structure and enzyme mechanism? Molecular genetics, on the other hand, focuses on the function and/or malfunction of molecular components and on information processing in living cells. The traditional modeling approach in biochemistry is differential equation–based enzyme kinetics. Modeling studies of one or a few enzymatic reactions at a time have been successfully applied to in vitro kinetics. It remains to be demonstrated, however, that this approach can be scaled up to an in vivo system of hundreds of reactions and species with thousands of parameters (Teusink *et al*., 2000). More importantly, it is not clear that this is the ideal approach for integrating biochemistry with molecular genetics.

The constraint-based modeling (CBM) approach circumvents several of these difficulties. It facilitates integration of experimental data of disparate types and from disparate sources while increasing the accuracy in its prediction. It does not require a priori knowledge (or assumptions) regarding all of the mechanisms and parameters for a given system. However, when a priori knowledge exists, such as data on enzyme kinetics or measurements of in situ concentrations and fluxes, this knowledge can be introduced in the form of constraints, on equal footing with molecular genetic observations on the topology and information flow in a biochemical network. While the differential equation–based modeling provides predictions with "high information content and high false rate", the CBM approach, by design, provides a low level of false prediction, but can often give little information in its prediction. Thus, we believe that these two approaches will ultimately prove to be complementary.

It is the aim of this chapter to review this alternative, constraint-based approach to modeling biochemical systems (Reed and Palsson, 2003). We shall focus on modeling of cellular metabolic networks, provide a comprehensive description of the mathematical and theoretical basis for CBM of metabolic systems. The material has been organized with the objective of a convenient exposition, rather than as an

historical account. Wherever possible, we point to detailed reviews on specialized topics.

2. Biochemical variables and constraints on fluxes

For metabolic systems, the variables of interest are the concentrations of biochemical species (c_i), the fluxes of the biochemical reactions (J_j), and the activities of the associated enzymes (X_j). Furthermore, metabolic fluxes are responsible for maintaining the homeostatic state of the cell, a condition that translates into the assumption that the metabolic network functions in or near a steady state, that is, all of the concentrations are treated as constant in time.

2.1. The mass-balance constraint

In a metabolic steady state, the biochemical fluxes are balanced to maintain constant concentrations of all internal metabolic species. If the stoichiometry of a system made up of M species and N fluxes is known, then the stoichiometric numbers can be systematically tabulated in an $M \times N$ matrix, known as *the stoichiometric matrix* $\widetilde{\mathbf{S}}$ (Clarke, 1980). The S_{ij} entries of the stoichiometric matrix are determined by the stoichiometric numbers appearing in the reactions in the network. For example, if the jth reaction has the form:

$$S_{1j}^{L} A_1 + \cdots + S_{Mj}^{L} A_M \rightleftharpoons S_{1j}^{R} A_1 + \cdots + S_{Mj}^{R} A_M \tag{1}$$

where A_i represents the ith species, then the stoichiometric matrix has the form $S_{ij} = S_{ij}^{R} - S_{ij}^{L}$.

The fundamental law of conservation of mass dictates that the vector of steady state fluxes, $\mathbf{J}$, satisfies

$$\widetilde{\mathbf{S}}\mathbf{J} = \mathbf{b} \tag{2}$$

where $\mathbf{b}$ is the vector of boundary fluxes that transport material into and out of the system. If the values of the boundary fluxes are not known, equation (2) can be written as $\mathbf{SJ} = \mathbf{0}$ in which the boundary fluxes have been incorporated into the $M \times (N + N')$ matrix $\mathbf{S}$, where N' is the number of boundary fluxes (Qian *et al*., 2003). As an example, consider a simple network of three unimolecular reactions:

$$A \overset{J_1}{\rightleftharpoons} B, \quad B \overset{J_2}{\rightleftharpoons} C, \quad C \overset{J_3}{\rightleftharpoons} A \tag{3}$$

where all reactions are treated as reversible; left-to-right flux is the direction defined as positive. The network of equation (3) is represented by the stoichiometric matrix:

$$\widetilde{\mathbf{S}} = \begin{matrix} A \\ B \\ C \end{matrix} \begin{bmatrix} -1 & 0 & +1 \\ +1 & -1 & 0 \\ 0 & +1 & -1 \end{bmatrix} \tag{4}$$

Next, consider that species A is transported into the system at rate b_A and species B is transported out at rate b_B. Then the mass-balance equations $\widetilde{\mathbf{S}}\mathbf{J} = \mathbf{b}$ can be expressed:

$$\begin{bmatrix} -1 & 0 & +1 \\ +1 & -1 & 0 \\ 0 & +1 & -1 \end{bmatrix} \begin{bmatrix} J_1 \\ J_2 \\ J_3 \end{bmatrix} = \begin{bmatrix} -b_A \\ +b_B \\ 0 \end{bmatrix} \tag{5}$$

Algebraic analysis of this equation reveals that mass-balanced solutions exist if and only if $b_A = b_B$. Equation (5) can be simplified to $J_2 = J_3 = J_1 - b_A$. Thus, mass balance does not provide unique values for the internal reaction fluxes. In fact, for this example, solutions exist for

$$J_1 \in (-\infty, +\infty), \quad J_2 \in (-\infty, +\infty), \quad J_3 \in (-\infty, +\infty) \tag{6}$$

Equation (6) illustrates the fact that often the mass-balance constraint poses an underdetermined problem; typically, it is necessary to identify additional constraints and/or to formulate a model objective function to arrive at meaningful estimates for biochemical fluxes.

2.2. *Thermodynamic constraints*

In addition to the stoichiometric mass-balance constraint, constraints on reaction fluxes and species concentration arise from nonequilibrium steady state biochemical thermodynamics (Hill, 1977). For a biochemical reaction at a constant temperature T, such as

$$A + B \rightleftharpoons C + D \tag{7}$$

there exists a forward flux J_+ and a backward flux J_-, with net flux $J = J_+ - J_-$. The concentrations of the reactants and products in this reaction are related to the chemical potential of the reaction via (Qian, 2001)

$$\Delta\mu = \mu_C + \mu_D - \mu_A - \mu_B = k_B \mathrm{T} \ln(J_-/J_+) \tag{8}$$

where k_B is the Boltzmann constant. We see from equation (8) that J and $\Delta\mu$ always have opposite signs, and are both zero only when a reaction is in equilibrium.

For a system of reactions, let $\Delta\mu$ be the vector that contains potential differences for all the reactions. The magnitude of the product $-\mathbf{J}\Delta\mu$ is the amount of heat the reactions dissipate per unit time. The negative sign reflects the Second Law of Thermodynamics according to Lord Kelvin: One cannot convert 100% of heat energy into useful work.

The fundamental law of conservation of energy (First Law of Thermodynamics) dictates that the heat dissipated by the reactions is supplied by constant feeding

of the *open* biochemical system. We have shown that this statement can be mathematically expressed as

$$\boldsymbol{\mu}\mathbf{J} = \boldsymbol{\Delta\mu}\widetilde{\mathbf{S}}\mathbf{J} = \boldsymbol{\mu}\mathbf{b} \tag{9}$$

where the right-hand side of equation (9) is the amount of energy supplied to the system through boundary fluxes (Qian *et al.*, 2003). If the system is closed by removing the boundary fluxes, Equation (9) becomes

$$\boldsymbol{\Delta\mu}\mathbf{K} = \mathbf{0} \tag{10}$$

where the matrix $\mathbf{K}$ contains a basis for the right null space of $\widetilde{\mathbf{S}}$. This relation reflects *energy balance*, a generalization of Kirchhoff's loop law and the Tellegen's theorem in electrical circuits (Beard *et al.*, 2002).

For the example of equation (3), equation (10) is expressed as:

$$[\Delta\mu_1\ \Delta\mu_2\ \Delta\mu_3]\begin{bmatrix}1\\1\\1\end{bmatrix} = 0 \tag{11}$$

Here, the matrix $\widetilde{\mathbf{S}}$ of equation (4), has a one-dimensional null space, for which the vector $[1\ 1\ 1]^T$ is a basis. Equation (11) corresponds to summing the reaction potentials about the closed loop formed by the reactions in Equation (3).

The requirement that J and $\Delta\mu$ for each reaction in a network have opposite signs provides a stringent constraint on the vectors $\mathbf{J}$ and $\Delta\mu$. Each vector $\mathbf{J}$ that satisfies mass balance $\widetilde{\mathbf{S}}\mathbf{J} = \mathbf{b}$ must also satisfy the following condition in order to be thermodynamically feasible. The system of inequalities

$$\sum_i \mu_i \widetilde{S}_{ij} J_j \leq 0,\ \ (j = 1, 2, \ldots, N) \tag{12}$$

must have at least one nonzero solution for $\{\mu_i\}$ (Qian *et al.*, 2003; Beard *et al.*, 2004).

Under this constraint, the bounds on the fluxes of equation (5) are narrowed from those of equation (6) to:

$$J_1 \in (0, b_A), \quad J_2 \in (0, b_A), \quad J_3 \in (0, b_A) \tag{13}$$

Thus, in general, the thermodynamic constraint narrows the feasible flux space, but not necessarily to a unique solution. Knowledge of the boundary fluxes translates into constraints on the reaction directions. Thus, the feasible reaction directions are a function of an open system's (i.e., a cell's) interaction with its environment.

Prior to the introduction to the generalized constraint-based thermodynamic theory outlined above, applications of constraint-based modeling of metabolic systems relied on an empirical set of irreversibilities that were obtained from prior observations of reaction directions in physiological settings. By treating certain reactions as

implicitly unidirectional, biologically reasonable results can often be obtained without considering the system thermodynamics as outlined above. Since the system-level thermodynamic constraint is inherently nonlinear, in current and future application of constraint-based modeling, it may be practical to implement unidirectional (irreversibility) constraints on specific reactions in large-scale network models.

3. Biochemical concentrations and enzyme activities

Combining mass balance with the thermodynamic constraint, one can determine the feasible ranges for the biochemical concentrations and the levels of enzyme activities.

3.1. Feasible biochemical concentrations from potentials

Introducing the chemical potential and the energy balance equation provides a solid physical chemistry foundation for the CBM approach to metabolic systems analysis. Proper treatment of the network thermodynamics not only improves the accuracy of the predictions on the steady state fluxes, but can also be used to make predictions on the steady state concentrations of metabolites. To see this, we substitute the well-known relation between the chemical potential μ and the concentration c of a biochemical species, $\mu = \mu_o + k_B \mathrm{T} \ln c$ into the equation (12):

$$\sum_i \ln c_i \widetilde{S}_{ij} J_j \leq -\Delta\mu_j^o \tag{14}$$

where $\Delta\mu_j^o$ is the standard state chemical potential difference for reaction j, which may be obtained from a standard chemical reference source. There is also a concerted effort to establish a central database for this information at the National Institute of Standard and Technology (NIST). If a solution for μ_i exists for equation (12), then there exists a set of corresponding concentrations c_i. In fact, equation (14) provides a feasible space for the metabolites concentrations as a convex cone in the log-concentration space. If the set of feasible concentrations is empty, then the vector $\mathbf{J} = \{J_j\}$ is thermodynamically infeasible.

3.2. Biochemical conductance and enzyme activity

From the traditional biochemical kinetics standpoint, both steady state biochemical concentrations and reaction fluxes are predictable from known enzyme reactions with appropriate rate constants and initial conditions. In steady state, the fluxes are computable from the concentrations of the reactants and products. However, a realistic challenge we confront is that our current understanding of the reaction mechanisms and measurements of rate constants are significantly deficient. From the standpoint of CBM, however, the ratio between the J_k and $\Delta\mu_k$ of a particular reaction is analogous to the conductance, which can be shown to be proportional

to the enzyme activity of the corresponding reaction. We emphasize that the magnitudes of both J_k and $\Delta\mu_k$ are functions of the reaction networks topology. Therefore, each one alone will not be sufficiently informative of the level of enzyme activity (i.e., the level activity due to gene expression or posttranslational modification).

3.3. Conserved metabolic pools

In addition to the constraint on concentrations imposed by equation (14), a reaction network's stoichiometry imposes a set of constraints on certain conserved concentration pools (Alberty, 1991). These constraints follow from the equation for the kinetic evolution of the metabolite concentration vector:

$$\mathbf{P}\frac{\mathrm{d}\mathbf{c}}{\mathrm{d}t} = \mathbf{SJ} \tag{15}$$

where $\mathbf{P}$ is a diagonal matrix, with diagonal entries corresponding to the partition coefficients, or fractional intracellular spaces, associated with each metabolite in the system. In equation (15), columns corresponding to the boundary fluxes have been grouped into the matrix $\mathbf{S}$. Here, the vector $\mathbf{J}$ includes both internal reaction fluxes and boundary fluxes. The left null space of the matrix $\mathbf{P}^{-1}\mathbf{S}$ may be computed and bases for this space stored in a matrix $\mathbf{L}$, such that:

$$\mathbf{L}\frac{\mathrm{d}\mathbf{c}}{\mathrm{d}t} = \mathbf{LP}^{-1}\mathbf{SJ} = \mathbf{0} \tag{16}$$

It follows from equation (16) the product $\mathbf{Lc}$ remains constant and defines a number of conserved pools of metabolic concentrations. For example, if we were to consider the glycolytic series as an isolated system, with no net flux of phosphate-containing metabolites into or out of the system, then as phosphate is shuttled among the various metabolites, the total amount of phosphate in the system is conserved.

3.4. Incorporating metabolic control analysis

One of the theoretical frameworks in quantitative analysis of metabolic networks is metabolic control analysis (Westerhoff and van Dam, 1987; Heinrich and Schuster, 1996). In metabolic control analysis, the enzyme elasticity coefficients provide empirical constraints between the metabolites concentrations and the reaction fluxes. These constraints can be considered in concert with the interdependencies in the $\mathbf{J}$ and $\mathbf{c}$ spaces that are imposed by the network stoichiometry. If the coefficients $\epsilon_k^i = (c_k/J_i)\partial J_i/\partial c_k$ are known, then these values bind the fluxes and concentrations to a hyperplane in the $\mathbf{J}$, $\mathbf{c}$ space. In addition, the constraint-based approach finds applications (Beard *et al*., 2003) in dynamic metabolic control

analysis, which derives flux control coefficients from linear relaxation kinetics in response to perturbations of a steady state (Reder, 1988; Liao and Delgado, 1993).

4. Optimization theory and objective functions

Constraint-based metabolic analysis is intimately tied to the mathematical field of optimization. Readers may find an accessible introduction to optimization theory, which represents a mature field of modern applied mathematics, in Strang's *Introduction to Applied Mathematics* (Strang, 1986). Optimization theory has been the major mathematical engine behind bioinformatics and genomic analysis (Waterman, 1995). Constraint-based approaches have also been very successful in biological structural modeling ranging from distance geometry calculations for protein structure prediction from NMR (*see* Article 105, **NMR**, Volume 6) to the recent structural determination of large macromolecular complexes (Alber *et al*., 2004). For the purposes of this chapter, it is sufficient to be familiar with the following basic concepts of optimization theory.

Mathematical optimization deals with determining values for a set of unknown variables $x_1, x_2, \ldots, x_n$, which best satisfy (optimize) some mathematical objective quantified by a scalar function of the unknown variables, $F(x_1, x_2, \ldots, x_n)$. The function F is termed the *objective function*; bounds on the variables, along with mathematical dependencies between them, are termed *constraints*. Constraint-based analysis of metabolic systems requires definition of the constraints acting on biochemical variables (fluxes, concentrations, enzyme activities) and determining appropriate objective functions useful in determining the behavior of metabolic systems.

Therefore, in CBM, the objective functions play a crucial role. A given objective function can be thought of as a mathematical formulation of a working hypothesis for the function of particular cell or cellular system. These objective functions should not be considered to be as theoretically sound as the physiochemical constraints; but they may be informative and biologically relevant. They can serve as concrete statements about biological functions and powerful tools for quantitative predictions, which must be checked against experimental measurements. One of the surprising discoveries in constraint-based modeling is how well certain simple objective functions have described biological function (see below).

That a cell functions precisely following some rule of optimality (such as optimal energetic efficiency for optimal cell growth rate) is, of course, highly suspect. There may be an evolutionary argument in favor of certain objective functions, but the ultimate justifications lie in the correctness of its predictions. In this sense, the constraint-based optimization approach provides a convenient way to efficiently generate quantitative predictions of biological hypotheses formulated in terms of objective functions. The value of this approach is in facilitating the systematic prediction–experimental verification–hypothesis modification cycle, ideally leading to new discoveries.

The aim of metabolic engineering is different from that of the traditional biological research (Bailey, 1991; Stephanopoulos, 1994). In metabolic engineering, one is more interested in the "capacity" and optimal behavior of a "biological

hardware" (Edwards and Palsson, 2000; van Dien and Lidstrom, 2002) rather than its natural function per se. For this reason, the metabolic engineering community has been a major proponent of the constraint-based optimization approach, while the cell biologists, whose traditional inclination follow reductionism, view the approach with certain healthy skepticism. Hopefully, with the introduction of thermodynamics, and the establishment of physiochemical basis of the CBM, the two communities will join force in furthering the research on Systems Biology of cells (Hartwell *et al*., 1999).

5. Applications of constraint-based modeling

For bacterial cells, growth rate (rate of biomass production) has been a widely used objective function. This objective is constructed as a net flux out of the cell of the components of biomass (amino acids, nucleotides, etc.) in their proper stoichiometric ratios, which translates into a linear function of the reaction fluxes. On the basis of this elegant paradigm, predictions from FBA of the fate of the *E. coli* MG1655 cell following deletions of specific genes for central metabolic enzymes have been remarkably accurate (Edwards and Palsson, 2000). When combined with energy balance analysis (EBA), it has been shown (Beard *et al*., 2002) that cells with nonessential genes deleted can redirect the metabolic fluxes under relatively constant enzyme activity levels, with few changes due to gene expression regulation and/or posttranslational regulation. The FBA/EBA combined approach predicts which enzyme must be upregulated, which must be down regulated, and which reactions must be reversed given perturbations to the genotype and/or cellular environment. Using this combined approach, a clear relation is established between the enzyme regulation and constraint-based analysis of metabolism.

Different objective functions can be used in studying other biological systems and problems. When addressing cellular metabolic pathway regulation, robustness has proven to be a useful concept. Robustness can be defined as minimal changes in metabolic fluxes, in steady state concentration, or in enzymes activities following perturbations. For example, minimization of flux adjustment has been used to model the metabolic response of *E. coli* JM101 with pyruvate kinase knockout (Segrè *et al*., 2002). In this study, it is assumed that the cell acts to maintain its wild-type flux pattern in response to the challenge imposed by a gene knockout. However, a minimal change in the flux pattern may require an unrealistic level of metabolic control. We have shown (Beard and Qian, 2005) that the objective of minimal changes in enzyme activities predicts the key regulatory sites in switching between glycogenic and gluconeogenic operating modes in hepatocytes. This approach facilitates inverse analyses, where the regulatory system is treated as a black box and control mechanisms are identified from measurements of the inputs and outputs to the system.

6. Summary

In summary, the constraint-based approach to the analysis of metabolic systems is based on a set of constraints that are imposed by the fundamental laws of mass

conservation and thermodynamics. These laws impose mathematical dependencies on the feasible fluxes, potentials, and concentrations in a given metabolic system. Biological hypotheses may be formulated as mathematical objectives that metabolic systems optimize under the imposed constraints. These hypotheses (e.g., optimal growth or optimally efficient control) are accepted, rejected, or revised on the basis of comparisons between the model predictions and experimental measurements.

Specialist Review

Metabolic dynamics in cells viewed as multilayered, distributed, mass-energy-information networks

Miguel A. Aon and Sonia Cortassa
The Johns Hopkins University, Baltimore, MD, USA

1. Introduction

The biological sciences are in the midst of a transition between an *analytical* and an *integrative* period. During the analytical period, researchers have unraveled the main macromolecular components of cellular machinery including the cytoskeleton, entire routes of intermediary metabolism, the circuitry involved in the expression of genetic information, and signal transduction pathways. This has generated significant amounts of information, most of which is contained in databases. The advent of functional genomics, following the sequencing of several genomes including human, is now producing an increased understanding of the functions of gene products at several levels (named as genome, transcriptome, proteome, and metabolome) (Oliver, 2000). Now we are challenged to address the question how a cell works during its main life stages, that is, growth, division, differentiation, and death. We would like to know how the mass-energy transformation and -information (genetic and signaling)-carrying networks in the cell interact with each other to produce cellular responses under defined physiological conditions. This view of the cell as a multilayered, distributed, mass-energy-information network (Figure 1) emphasizes that information processes pervade all levels from genome to metabolome. Furthermore, it points out where the main gap in our knowledge stands and why our efforts should be directed to answer questions such as the way in which cellular phenotype dynamically “emerges” from the mass-energy-information carrying networks of the cell.

2. Mathematical models: criteria of reliability

Mathematical models are now playing a major role at integrating information across the molecular, cellular, tissue and organ levels, in order to improve our

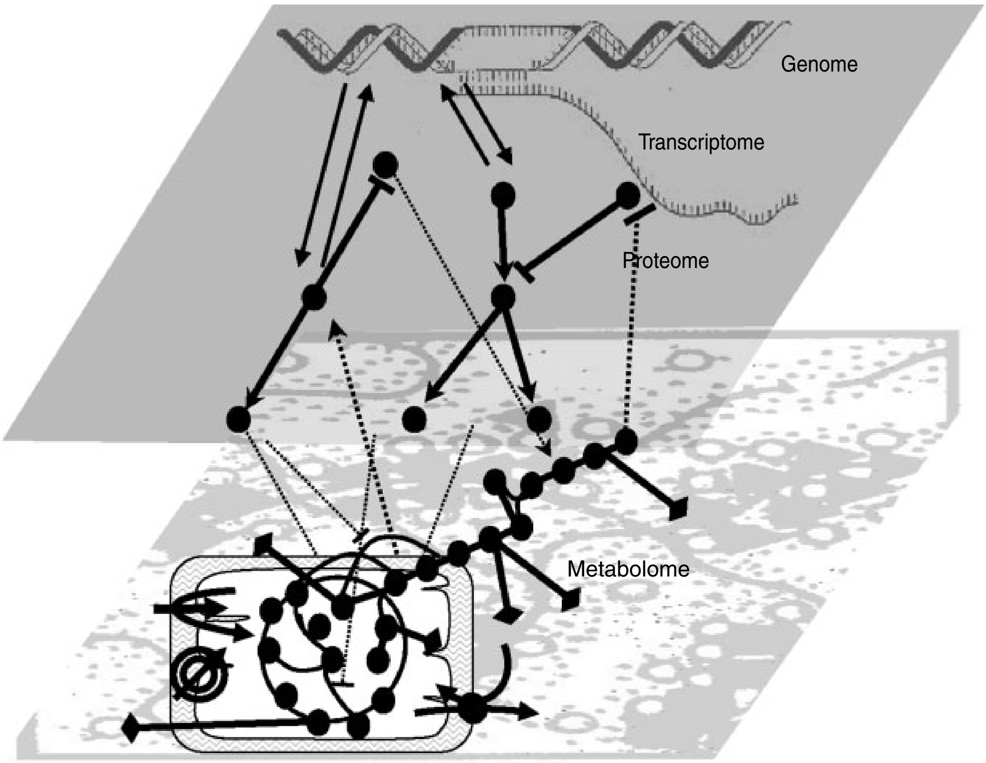

Figure 1 A view of cells as multilayered mass-energy-information networks of reactions. Metabolic reactions embedded in the cytoplasmic scaffolds are shown diagrammatically with each chemical species represented by a filled circle (bottom layer). Central catabolic pathways (glycolysis, TCA cycle) and mitochondria are sketched. As an example, mitochondria emphasize the interaction between subcellular compartments through transport reactions and exchange of metabolites or intracellular messengers that take part of information-carrying networks. The chemical reaction network for the synthesis of a microorganism is a complex one comprising around 1000 chemical reactions (Alberts *et al*., 1989). A typical mammalian cell synthesizes more than 10 000 different proteins, a major proportion of which are enzymes that carry out the mass-energy transformations represented in the bottom-layer networks. The information processing function of cells is carried out by other networks, that is, signaling pathways and the regulatory circuitry related with gene expression (genome, represented in the top layer), intertwined with the network depicted in the bottom layer. The information-carrying networks are shown in a different layer just for the sake of clarity and its presence on top does not imply hierarchy. On the contrary, as emphasized by arrows, cross-talk connections exist between all layers (activating, with arrowheads, or inhibitory, with a crossed line). Nevertheless, each network has its own type and mechanisms of interactions, for example, the nodes on the top layer are proteins or second messengers. The proteins (proteome) are continuously synthesized from mRNA (transcriptome) through transcription and translation mechanisms of gene expression, and exert feedback regulation (e.g., DNA-binding proteins) on its own, or the expression of other proteins (depicted as double arrows on top layer). Moreover, proteins taking part of the cytoskeleton either exert feedback regulation on its own expression (e.g., modulation of intracellular levels of tubulin through the stability of mRNAs) (Cleveland, 1988), or influence metabolic fluxes through epigenetic mechanisms (e.g., (de)polymerization, dynamic instability) (Reproduced from Cortassa *et al*. (2002) by permission of World Scientific Publishing)

understanding of biological function in general and specific processes operating in vivo in a defined context. Reliability of the integrative power of mathematical models is reflected in the following main properties: (1) whether or not there is a sound physico-(bio)chemical basis for the models; (2) the ability of the model to reproduce reported experimental evidence; (3) the ability of the model to provide insights into biophysical/biochemical processes (explanatory power); and (4) ability of the model to predict novel behaviors.

Figures 2 and 3 show several of the tests according to criteria (1–4) mentioned above. An integrative model of mitochondrial energetics, calcium dynamics, and reactive oxygen species (ROS) production and scavenging (Cortassa *et al*., 2003; Cortassa *et al*., 2004) serve to illustrate these four criteria:

1. *Sound physico-(bio)chemical basis*: Stimulation of respiration by ADP has been proposed as one of the mechanisms by which mitochondrial ATP production meets the cellular ATP demand (Chance and Williams, 1956; Harris and Das, 1991). The integrated model simulates the expected relationship between mitochondrial membrane potential, $\Delta\Psi_m$, and respiration upon a transition between states 4 (absence of ADP that leads to null ATP synthesis and low respiration) and 3 (presence of ADP leading to maximal ATP synthesis and high respiration).
2. *Ability to reproduce reported experimental evidence*: The integrated model of mitochondrial energetics is capable of simulating time-dependent behavior under two relevant physiological situations: (1) NADH and Ca^{2+} dynamics in mitochondria of heart trabeculae subjected to changes in workload (Brandes and Bers, 2002) (Figure 2a–c); (2) the dynamics of respiration following a shift between states 4 and 3 after a pulse of ADP (Boveris *et al*., 1999) (Figure 3c).

   Recent development of the integrated model of mitochondrial energetics and Ca^{2+} dynamics includes mitochondrial ROS production, cytoplasmic ROS scavenging, and ROS activation of inner membrane anion flux. This upgraded model is able to simulate the period and phase of mitochondrial oscillations in $\Delta\Psi_m$, NADH, and ROS (Cortassa *et al*., 2004) in agreement with experimental data obtained in heart cells under oxidative stress (Aon *et al*., 2003).
3. *Explanatory power*: The participation of various regulatory interactions was made clear in the analysis of the time-dependent behavior of Ca^{2+} and NADH in heart trabeculae during changes in workload. Model simulations mimicking the participation of just one of the regulatory mechanisms established that: (1) the recovery phase of NADH level after a sudden increase in pacing frequency is due to the stimulatory effect of Ca^{2+} on the tricarboxylic acid (TCA) cycle dehydrogenases and (2) the fast response of the NADH under(over)shoot following an increase (decrease) in pacing frequency is related to the stimulation of respiration by changes in mitochondrial ADP. Thus, the model results suggest a coparticipation of Ca^{2+} and ADP to explain mitochondrial NADH dynamics during an increase in workload (Figures 2 and 3).
4. *Predictive power*: The computational mitochondrial model has made several predictions, which have been verified experimentally. These predictions include: (1) modulation of the period of the mitochondrial oscillator described in heart cells by altering the concentration of ROS scavengers or the rate of oxidative

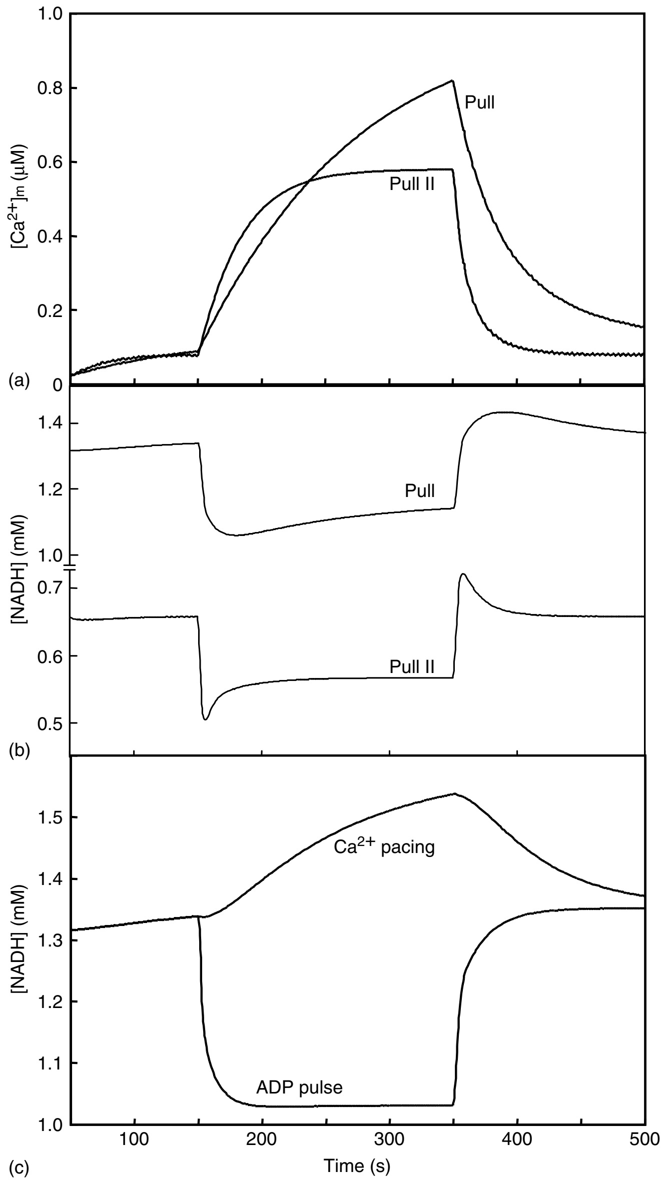

Figure 2 Time-dependent behavior of mitochondrial Ca^{2+} and NADH after changes in workload according to an integrated model of mitochondrial energetics. Model response of mitochondrial Ca^{2+} (a) to the pacing protocol applied at low frequency (0.25 Hz) for 100 s, and then a high frequency (2 Hz) for 200 s, followed by a return to the low frequency. (b) Time course of NADH levels during changes in pacing frequency, simulated by increasing the Ca^{2+} pulse frequency combined with an increase in ADPi. (c) The effects of a change in Ca^{2+} pulse frequency or ADPi applied separately. The simulations reproduce the experimental data reported by Brandes and Bers (2002) for rat cardiac trabeculae subjected to the same pacing protocol as in the simulations. "Pull" corresponds to a parametric condition in which processes downstream NADH control the respiratory flux (Reproduced from Cortassa *et al*. (2003) by permission of Biophysical Society)

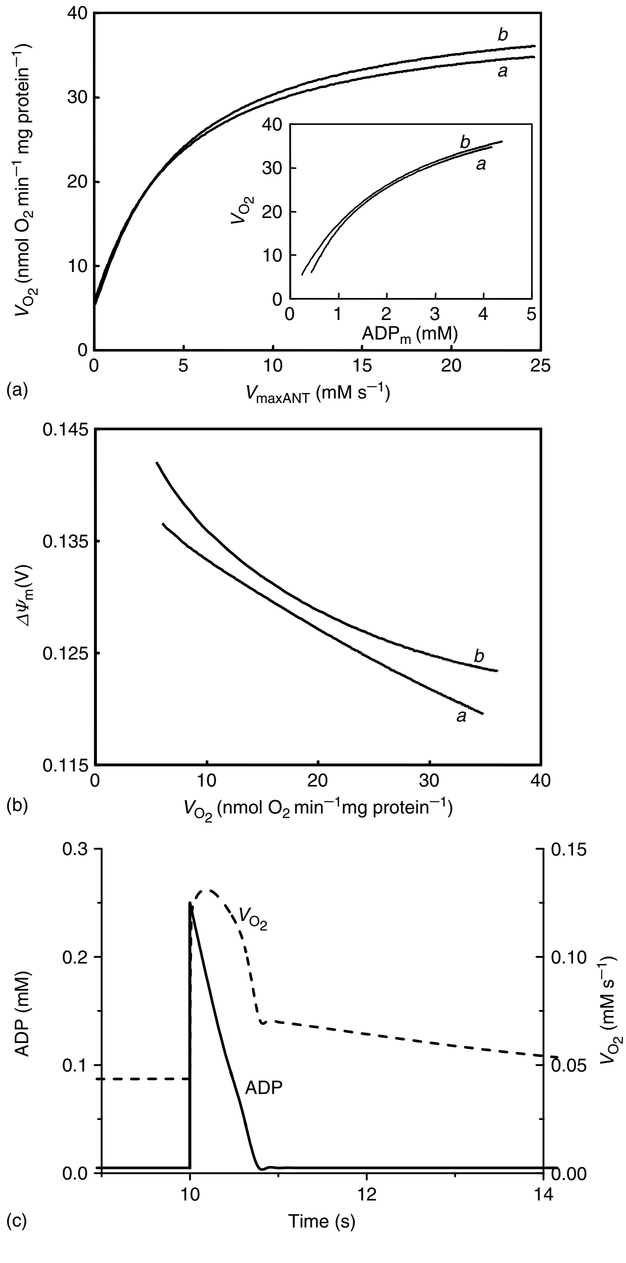

Figure 3 Relationship between membrane potential, $\Delta\Psi_m$, and respiratory flux, V_{O2}, upon changes in adenine nucleotide translocator (ANT) activity, and the transition from state 4 to state 3, obtained with an integrated model of mitochondrial energetics. The changes in V_{O2} and $\Delta\Psi_m$ are determined by the behavior of the model according to a steady state analysis performed at different ANT maximal activities (V_{maxANT}) that result in different ADP$_m$ concentrations (a, inset). The left portion of curves *a* and *b* in (a) and (b), corresponds to mitochondria in state 4 (i.e., low ADP) and the increase in V_{O2} results from the respiratory control exerted by augmenting ADP concentrations. (c) Model simulation of the transition state 4 → state 3 after a pulse of 0.25 mM ADP (Panels a and b are reproduced from Cortassa *et al*. (2003) by permission of Biophysical Society)

phosphorylation and (2) that the redox state of the glutathione pool oscillates (Cortassa *et al*., 2004). Another remarkable (yet untested) prediction of this model is that the mitochondrial oscillator of heart cells would be able to modulate its period over a wide range, from milliseconds to hours (Cortassa *et al*., 2004). This opens the possibility of a role of mitochondrial oscillations in intracellular signaling or timekeeping since bursts of ROS are a primary output of the mitochondrial oscillator. There is widespread evidence that many signaling and transcriptional activation cascades respond to ROS (Dröge, 2002; see the following text).

3. Mathematical models: the road to quantitation

Quantitation of cellular metabolism is one of the main facets that characterize the *integrative* period of biology. After most of the metabolic pathways were described and their constituent enzymes kinetically characterized, the road was paved for quantitation. Three main theoretical developments opened the way for a quantitative analysis of metabolism: kinetic modeling, metabolic control analysis (MCA), and metabolic flux analysis (MFA). Each of these theoretical developments was achieved during the second half of the past century. We will refer to the two former developments since MFA is reviewed elsewhere in this volume (*see* Article 112, **Constraint-based modeling of metabolomic systems**, Volume 6).

3.1. Kinetic modeling

This modeling technique is expanding and becoming a common tool for gaining mechanistic insight into important biological phenomena (Figures 2 and 3). Several efforts such as the insulin secretion in pancreatic β-cells (Magnus and Keizer, 1998), receptor-triggered cell signaling and cell communication during proliferation, migration, and cellular differentiation (Wiley *et al*., 2003), circadian rhythms (Goldbeter, 2002), or ultradian clocks (Lloyd *et al*., 2002) are worth mentioning. Many of these research efforts emphasize quantitative rather than qualitative data, and provide accurate tests for hypothesis-driven research (Winslow *et al*., 1999; Phair and Misteli, 2001; Tomita, 2001; Endy and Brent, 2001; Hasty *et al*., 2002; Slepchenko *et al*., 2002; Weiss *et al*., 2003).

Kinetic modeling of signaling networks is a timely topic for cell function (Bhalla, 2003; *see also* Article 108, **Functional networks in mammalian cells**, Volume 6 and Article 117, **EGFR network**, Volume 6). From the perspective of metabolic dynamics, the information-carrying networks often function transiently, under time frames fast enough for protein synthesis to be significant. Such is the case of cells subjected to sudden environmental changes where covalent modification by kinases activates production of allosteric effectors (AMP:ATP), or enzymes sense ratios of key allosteric metabolites (3PGA/Pi) producing an ultrasensitive amplification of entire metabolic pathways (Gomez-Casati *et al*., 2003; Hardie and Hawley, 2001; Vaseghi *et al*., 2001; Marsin *et al*., 2000; Marsin *et al*., 2002), or transcription factors whose critical cysteine residues are oxidized result in decrease of gene

promoter activity and subsequent gene expression (Morel and Barouki, 1999 and references therein).

In our view of cells as multilayered mass-energy-information networks of reactions (Figure 1), kinetic modeling is a basic tool for understanding their dynamics and control (Figures 2 and 3). This highlights the importance of being able to quantify the control and regulation of reaction networks in organelles and cells. Metabolic Control Analysis has provided these tools.

3.2. *Metabolic control analysis (MCA)*

Independently developed by Kacser and Burns (1973) and Heinrich and Rapoport (1974) elaborating on the work of Higgins (1965), this quantitative methodology has been extended and improved (see Fell, 1997; Cortassa *et al*., 2002, for reviews). Several aspects of control and regulation in metabolic networks have been quantified and conceptually refined, using MCA as a tool.

MCA addresses the question of what controls, and to what extent, the flux through a metabolic pathway at the steady state. Considering the mass-energy-information networks associated with mitochondrial energy production and regulation (Figure 4), we will illustrate how MCA is applied. In this particular case, relevant questions are: what controls the respiratory flux? and what controls relevant metabolite and ion concentrations such as ADP and Ca^{2+}? The latter question is relevant since ADP and Ca^{2+} play an important role as effectors in the regulation of several nodes in the network. More specifically, ADP for F_1F_0-ATP synthase and succinyl CoA lyase, and Ca^{2+} for the TCA cycle enzymes α-ketoglutarate (KGDH) and isocitrate (IDH) dehydrogenases. In this way, ADP and Ca^{2+} take part of the information-carrying networks as second messengers and allosteric effectors.

According to MCA, control is quantified through two different types of coefficients: the flux control coefficient and the elasticity coefficient. Both coefficients represent either systemic (flux control) or local (elasticity) properties of the network and its components, respectively. In mitochondria, the control exerted by each network component on the respiratory flux at the steady state is quantified by the flux control coefficient (Kacser and Burns, 1973; Heinrich and Rapoport, 1974):

$$C_{E_k}^{J_i} = \frac{\mathrm{E_k}}{\mathrm{J_i}} \frac{\partial J_i}{\partial E_k} \tag{1}$$

where the flux control coefficient, $C_{E_k}^{J_i}$, is the fractional change in respiratory flux (J_i) in response to a fractional change in a parameter of the system, typically an enzyme concentration, E_k. Similarly, a metabolite, M_i, concentration control coefficient, $C_{E_k}^{M_i}$, is defined:

$$C_{E_k}^{M_i} = \frac{\mathrm{E_k}}{M_\mathrm{i}} \frac{\partial M_i}{\partial E_k} \tag{2}$$

The link between the kinetic properties of an enzyme and its potential for flux control is given by the elasticity coefficient, ε, through the connectivity theorem (Fell, 1997; Cortassa *et al*., 2002). The elasticity coefficient ε_{ij} quantifies the effect of ionic species, or intermediate metabolite S (e.g., α-ketoglutarate) on the velocity

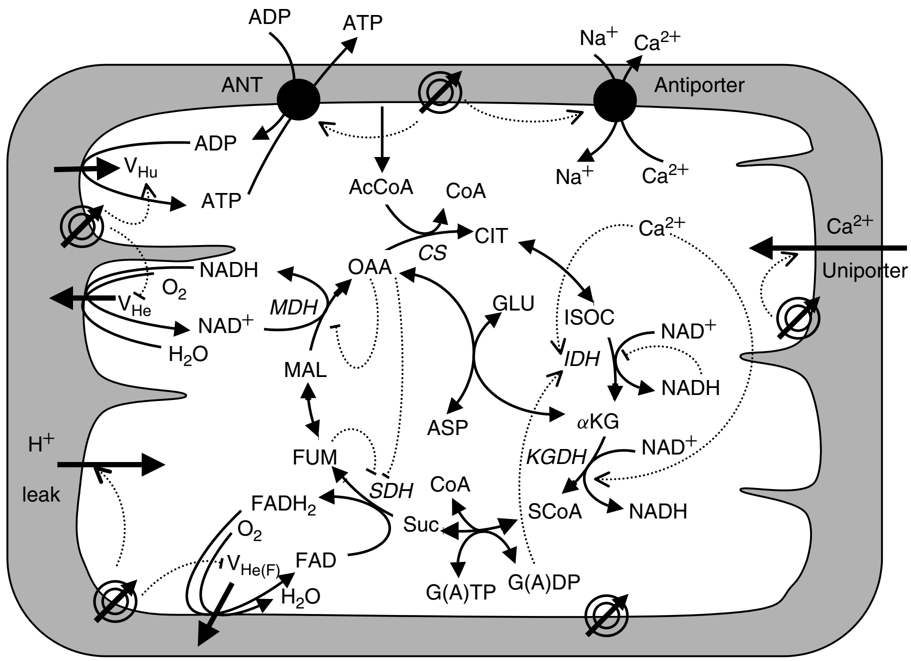

Figure 4 Schematic representation of electrophysiological and metabolic processes and their interactions, as described by an integrated model of mitochondrial energy metabolism (Cortassa *et al*., 2003). The model takes into account oxidative phosphorylation and matrix-based processes in mitochondria. The tricarboxylic (TCA) cycle of the mitochondrial matrix is fed by acetyl CoA (AcCoA). The TCA cycle oxidizes AcCoA to CO_2 and produces NADH and $FADH_2$, which provide the driving force for oxidative phosphorylation. NADH and $FADH_2$ are oxidized by the respiratory chain, and the concomitant pumping of protons across the mitochondrial inner membrane establishes an electrochemical gradient, or proton motive force ($\Delta\mu_H$). This proton motive force drives the phosphorylation of matrix ADP to ATP by the F_1F_0-ATPase (ATP synthase). The $\Delta\Psi_m$ of the inner membrane also governs the electrogenic transport of ions, including the cotransport of ATP and ADP by the adenine nucleotide translocator, Ca^{2+} influx via the Ca^{2+} uniporter and Ca^{2+} efflux via the Na^+/Ca^{2+} antiporter. The model also accounts for the explicit dependence of the TCA cycle enzymes isocitrate dehydrogenase (IDH) and α-ketoglutarate dehydrogenase (KGDH) on Ca^{2+}. Key to symbols: The concentric circles with an arrow across located at the inner mitochondrial membrane represent the $\Delta\Psi_m$. Dotted arrows indicate regulatory interactions either positive (arrow head) or negative (−) (Reproduced from Cortassa *et al*. (2003) by permission of Biophysical Society)

v_i of enzyme E_i (e.g., α-ketoglutarate dehydrogenase) is:

$$\varepsilon_S^{v_i} = \frac{\mathrm{S}}{v_i}\frac{\partial v_i}{\partial \mathrm{S}} \tag{3}$$

being the elasticity coefficient, $\varepsilon_S^{v_i}$, the fractional change in rate of the isolated enzyme, ∂v_i, in response to a fractional change, ∂S, in the amount of effector, S.

When MCA was applied to elucidate the control of mitochondrial respiration, two major conditions of mitochondrial physiology were found and defined as “push” or “pull” (Table 1, see also Cortassa *et al*., 2003). A “push” condition happens when the steps controlling the respiratory flux are upstream NADH (e.g., TCA cycle), whereas “pull” corresponds to a situation in which respiration is

Table 1 Control of the respiratory flux by TCA cycle enzymes and the rates of membrane-associated processes[a]

	Parametric set, flux control coefficient	
	Push	Pull
TCA cycle		
Citrate synthase (CS)	0.33	0.35
Isocitrate dehydrogenase (IDH)	22.8	5.3
α-ketoglutarate dehydrogenase (KGDH)	70.0	0.3
Malate dehydrogenase (MDH)	3.6	13.9
Membrane-associated processes		
Adenine nucleotide translocator (ANT)	3.8	38
Respiratory electron carriers	2.1	6.7
F_1F_0-ATPase	−0.2	2.7
Proton leak	0.1	0.3

[a]Control exerted by the rate of each process on mitochondrial respiration is quantified around the steady state corresponding to two set of parameters (Cortassa *et al*., 2003). The flux control coefficient (in %) indicates to which extent the respiratory flux changes upon a change on the activity of an enzyme in the pathway (see text equation 1). The flux control coefficient was calculated from the slope of the double logarithmic plot of V_{O2} as a function of the process rate under study.
In the cases of CS, IDH, KGDH, and MDH, the k_{cat} is varied around the steady-state level (<5% change) in order to compute the control coefficient. ρ^{res} and ρ^{F1} are varied (<10% change) to compute the control exerted by respiratory electron carriers and the F_1F_0-ATP synthase, respectively. The control exerted by the adenine nucleotide translocator and the proton leak is performed with parameters V_{maxANT} and g_H, respectively (Cortassa *et al*., 2003) (Reproduced from Cortassa *et al*. (2003) by permission of Biophysical Society).

controlled by processes downstream NADH (e.g., adenine nucleotide translocator, ATPase, respiration itself) (Table 1). Under “push” conditions, the Ca^{2+}-sensitive dehydrogenases (KGDH and IDH) of the TCA cycle share the control of respiration with 70% and 23%, respectively. For this situation, Ca^{2+} stimulates the rates of KGDH and IDH in the TCA cycle, and, in turn, the rates of respiration and F_1F_0-ATP synthase (Cortassa *et al*., 2003). This is an important point since it illustrates the difference between control and regulation, that is, respiration in mainly *controlled* by KGDH and IDH and *regulated* by Ca^{2+}. Flux control indicates the influence of the rate of a metabolic reaction or a biological process on a flux, whereas regulation refers to the modulation of an enzyme activity or pathway in response to the change in the level of a metabolite or ionic species. The difference is reflected in the way these concepts are quantitatively estimated. In our example, the regulatory effect of Ca^{2+} is quantified by the elasticity (equation 3) of the KGDH rate to Ca^{2+} (Figure 5), whereas control is quantified by the flux control coefficient (equation 1). A close inspection of Figure 5 shows that the initial reaction rate response of KGDH with respect to its substrate, α-ketoglutarate, exhibits substantial elasticity to Ca^{2+} within the concentration range detected in the mitochondrial matrix for the latter. This point also illustrates the importance of knowing the control exerted by different nodes in the network on Ca^{2+} or ADP concentration (quantified by the metabolite concentration coefficient, equation 2),

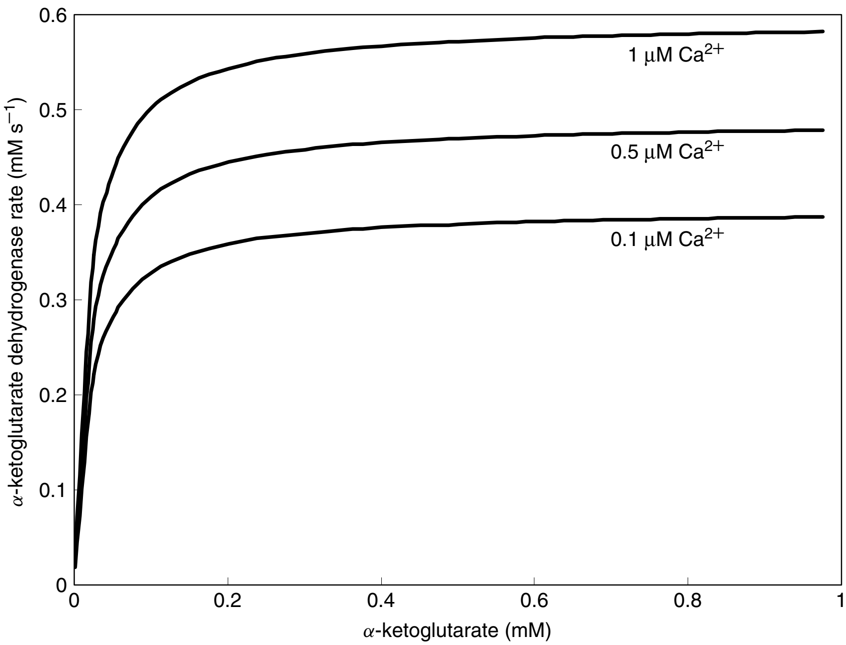

Figure 5 α-ketoglutarate dehydrogenase dependence on α-ketoglutarate and Ca^{2+}. The rate of KGDH is plotted against α-ketoglutarate concentration at various levels of Ca^{2+} as reported in Cortassa *et al*. (2003). The increase in V_{max} attained by the enzyme at saturating substrate levels indicates a positive elasticity of the enzymatic rate with respect to Ca^{2+} levels in the physiological range (Reproduced from Cortassa *et al*. (2003) by permission of Biophysical Society)

that is, their target enzymes will be responsive to the effector depending on its level.

The weight of the respiratory flux control shifts downstream of NADH ("pull") where the respiratory chain itself (i.e., through the concentration of electron carriers) and the adenine nucleotide translocator become the most rate-controlling steps (Table 1).

When targeting gene products differentially expressed in the disease state, the potentiality of MCA for detecting the main rate-controlling or regulatory steps in integrated metabolic systems becomes evident. For pathology, one would like to target the main determinants of a particular disease. In this sense, unique possibilities are open for the rational design of cells (Cortassa *et al*., 2002), or of effective therapeutic strategies (Cascante *et al*., 2002).

4. Proteomics and cell physiology: redundancy, control, and regulation

The changes in protein amounts and quality under defined conditions are main pieces of evidence provided by proteomics (Kovarova *et al*., 2002; Beranova-Giorgianni *et al*., 2002). This information can be very powerful when allied with

the theoretical concepts described before. As a matter of fact, many proteins have enzymatic activity. From the point of view of MCA, if the amount of an enzyme changes it may result in a change in the control of the flux. However, if the amount of an enzyme or protein remains unchanged it does not necessarily rule out its importance for regulation. Usually, regulatory enzymes in a metabolic network do not control the flux but exhibit high elasticity, or are responsive to an effector. Usually, these effectors are cofactors such as, for example, ATP, NAD(P)H, intracellular messengers (e.g., cAMP, Ca^{2+}), or a physiological condition (e.g., pH). If the control exerted by a protein on a metabolic network is known or can be known, then proteomics may highlight the importance of the role played by that protein in a well defined condition. Thus, proteomics combined with mathematical models will help elucidate the control aspects of metabolism.

Another important issue for cell physiology concerns the proteins that do not change or functionally redundant ones (i.e., different proteins may execute the same function). Crucial mechanisms such as energy provision in cells tend to be redundant conferring robustness to cells (Bailey, 1999). Bioenergetics is an excellent example of this. Considering the functional implications for cells under normal physiological conditions, proteins that do not change imply that they take part of vital mechanisms that tend to have little control on cell function, precisely because of that importance. In the same sense, a current misconception associated with adenine nucleotides is that they cannot be important because their concentrations hardly vary (Hardie and Hawley, 2001). Thus, cellular energetics and all its protein machinery constitute a compelling case illustrating the validity of the concept of redundancy (Koefoed *et al*., 2002).

5. Cytoplasmic organization: the missing link

The reliability of metabolic networks is firmly rooted in organization as well as redundancy. By the former, we mean supramolecular organization given by the cytoskeleton and protein–protein homologous or heterologous associations. Parallel pathways of identical function represent redundancy.

Since the beginning of the 1970s, compelling experimental evidence showed that enzymes are associated to other macromolecules in the cytoplasm of cells (Welch, 1977; Clegg, 1984; see Aon and Cortassa, 1997, for a review). These findings and the numerous reports derived from them progressively led to the idea that the physical chemistry of cellular cytoplasm is characterized by (supra)molecular organization and crowding (Aon *et al*., 2000; Ovadi and Saks, 2004). To this regard, at least two main ideas concerning the organization of metabolism in cells have emerged in the last decades: (1) metabolic channeling, in which reactions are facilitated by product/substrate transfer between closely associated enzymes (stable or transient enzymatic complexes) (Ovadi and Srere, 2000; Ovadi and Saks, 2004) and (2) cytoskeleton-driven modulation of enzymatic fluxes (Aon and Cortassa, 1997; Aon *et al*., 2000). Importantly, the kinetic properties of enzymes change during their association with macromolecular complexes composed of other enzymes or macromolecules taking part of the cytoskeleton or in cellular scaffolds.

In this sense, the cytoskeleton takes part of the information-transduction networks of cells (Aon and Cortassa, 2002).

The fractal organization exhibited by cytoskeletal proteins (Aon and Cortassa, 1994), and mitochondrial networks' physiology (Aon *et al*., 2004a) is a key ingredient for the scaling (power law) behavior exhibited by the connectivity of metabolites (Wagner and Fell, 2001; Bray, 2003) or mitochondrial networks at criticality (Aon *et al*., 2004b). The consequences for cellular (patho)physiology (O'Rourke, 2000) emerging from this "top-down" view must be further explored. Recent theoretical studies suggest that fractal organization allows enzyme reactions, following Michaelis–Menten or allosteric type kinetics, exhibits higher rates and sensitivity amplification in fractal media (for short times and at low substrate concentrations) than in Euclidean media (Aon *et al*., 2004a). These findings point out that owing to their fast kinetics, molecular mechanisms qualify for conferring fast and modulated response to cells facing environmental challenges (Koshland, 1987; Gomez-Casati *et al*., 2003). This feature is crucial when cells should adapt their energetics and signaling mechanisms following sudden changes in workload (Appaix *et al*., 2003) as in heart, or substrate supply (Vaseghi *et al*., 1999) or cell cycle dynamics (Müller *et al*., 2003) as in yeast cells.

6. Conclusions

6.1. The future of metabolic networks: a prospective

Jacob and Monod (1961) first proposed the metaphor of the genetic program as one entirely contained within the genomic DNA sequence. However, paraphrasing Fox Keller (2000), "If we wanted to keep the computer metaphor, we could describe the fertilized egg as a massively parallel and multilayered processor in which both programs (or networks) and data are distributed throughout the cell. (. . .) In this distributed program all the various DNA, RNA, and protein components function alternatively as instructions and data." This is in agreement with the view of cells as multilayered, distributed, mass-energy-information networks (Figure 1).

Many would agree that "cells are robust systems insensitive to many mutations, particularly those affecting 'core' activities" (Bailey, 1999). However, reported evidence also shows that several gene mutations affect more (sometimes seemingly unrelated) processes than the ones supposed to be targeted by the mutation. Conspicuous examples are given by cell-cycle genes affecting catabolite repression and, vice versa, catabolite repression genes influencing cell-cycle behavior (Mónaco *et al*., 1995; Aon and Cortassa, 1998); antisense inhibition of a plastidial isoform of adenylate kinase (unrelated, in principle, to the starch pathway) resulted in an increase in starch to 60% above that found in wild type (Regierer *et al*., 2002); or lack of correlation even between metabolites only separated by a single enzymatic step (Carrari *et al*., 2003). These lessons suggest caution when one annotates metabolic pathways (usually the mass-energy carrying ones) from genomic information as usually carried out with Metabolic Flux Analysis. This is due to the following reasons (see Cortassa *et al*., 2002, for several examples):

(1) some complex metabolic phenotypes are the outcome of multiple interacting genes and the environment; (2) the phenotypic consequences of gene inactivation depend on genetic background and pleiotropic effects; (3) pleiotropy may also arise through the strategic function of a gene product deeply nested in the mass-energy or information networks; (4) the missing information concerning regulatory interactions and signaling pathways that link all layers as shown in Figure 1.

The presumption that changes observed in vitro for enzymes or proteins do not necessarily happen under cellular conditions, points out that two main features representing the physicochemical condition of the cytoplasm ((supra)molecular organization and crowding) are not represented in the test tube. However, enzyme-mediated signal amplification has been shown to happen, or be modulated by cytoskeletal proteins or molecular crowding under in vitro or in situ conditions. These properties of individual enzymes' regulation when integrated in metabolic networks allow the emergence of new, unexpected, behaviors such as coherence and robustness (Aon and Cortassa, 2002).

Overall, the present state of knowledge dictates the necessity of a more profound understanding of the role and dynamics of information (signaling) networks as they relate to gene expression, under normal or pathophysiological conditions. Compelling experimental evidence points out the importance of accounting for cytoplasmic organization such as compartmentation, channeling, enzyme-cytoskeleton interaction, and crowding, in our mathematical models.

6.2. The evolution of mathematical models

There will be a survival of some of the mathematical models that are, and will be, proposed to do the task of integrating and making sense of the overflowing biological information. The survival of the fittest for mathematical models will be given by how closely interdependent have theory and experiment been during model construction provided the four main conditions for model reliability are fulfilled. In this way, we will be able to unfold the full potential of our models at descriptive, explanatory, and predictive levels, and through this, the organized complexity of nature.

While synthesizing biological information into a coherent scheme, there is a trade-off to be accomplished between *completeness* and *understandability*. We still have a long way to go to apprehend the fundamental role of signaling networks and cytoplasmic organization on cell function, a task for which mathematical modeling is unavoidable. We have greatly developed our ability to be more *complete* at integrating biological data. However, by doing so we may reach levels of trade-off between completeness and understandability that are beyond the reach of our present knowledge. We believe that there is much more room to accomplish the mentioned trade-off than any previous theoretical argument will suggest us to believe. However, at this point it is useful to remember that the *complete* simulation of a cell could involve a program whose description is *as large and complex as the cell itself*. As Barrow (1999) put it: "It is like having a full-scale map, as large as the territory it describes: extraordinarily accurate; but not so useful, and awfully tricky to fold up". The interpretation of the in silico behavior of such a cell may

well be beyond our understanding. Thus, at some stage of the *integrative* period of biology the important question to answer will be: do we have any tool(s) to keep the trade-off between completeness and understandability optimal enough and still retain the possibility of a significant and accessible knowledge of how a cell works? This is largely the problem that will be elucidated in the decade(s) to come.

Specialist Review

A complex systems approach to understand how cells control their shape and make cell fate decisions

Donald E. Ingber and Sui Huang
Harvard Medical School and Children's Hospital, Boston, MA, USA

1. Introduction

Systems Biology emerged from our increasing awareness that the study of individual genes, proteins, and pathways cannot explain the characteristic behaviors of biological systems as a whole. In this chapter, we focus on the challenge of understanding how the myriad of molecular pathways in living cells are coordinated so as to give rise to switches between the different discrete system-level behaviors of cells in multicellular organisms, such as proliferation, differentiation into one of a finite number of specialized cell types, cell migration or apoptosis. We also discuss how this whole-cell behavior is linked to the physical shape of cells – a connection that is crucial for the formation of tissue patterns.

Systems biologists take various approaches to address the problem cellular regulation (Huang, 2004). Some see in a systems approach the comprehensive detailed characterization of all molecular processes using the burgeoning massively parallel, high-throughput analytical methods. Although such approaches are indispensable, their goal still remains gene-centered in nature (Bray, 2003). The notion here is that an exhaustive description at the highest possible resolution of mechanistic details of a system equals the understanding of that system. In contrast to this "bottom-up" approach, other investigators who typically come to Systems Biology from fields outside classical molecular biology often take a "top-down" approach. Their main goal is to extract generalizable (even "universal") principles that govern the behavior of complex biological systems without specifying the identity of individual molecular players. One central premise here is that higher-order systems-level features that result from multicomponent interactions (von Bertalanffy, 1969; Bar-Yam, 1997) cannot be understood by studying the properties of the individual components or groups of components (e.g., signaling modules) alone – be it qualitatively by traditional biochemistry, or quantitatively by computational modeling. A first step in this approach is to

recognize and characterize the sometimes abstract higher-order qualities or patterns of behavior at the whole-system level. It is noteworthy that this top-down approach of Systems Biology is distinct from classical organismal biology that similarly studies biological behavior at a higher level, in that now we have access to the molecular component parts, and hence seek to understand the nature of the relationship between them and the integrated, system-level features.

Thus, our group has raised the molecular analysis of how mammalian cells decide whether to grow, differentiate, migrate, or die to that of a systems-level, top-down approach. In this chapter, we review work addressing the following fundamental questions: (1) How do interactions between different molecular filaments within structural networks, such as the cytoskeleton, lead to the production of living cells and tissues with characteristic shapes and mechanical properties? (2) How do regulatory interactions among genes and proteins produce a coherent information processing machinery that enables cells to sense multiple simultaneous inputs and orchestrate a concerted response? and (3) How do changes in cell structural networks impact these information processing networks? In addressing these questions, we will describe two integrating concepts of how cells organize their structural and information networks, which may explain system-level (whole cell) properties from interactions among multiple subcomponents.

2. Cell hardware: tensegrity as a design principle

Current understanding of cell and tissue regulation is explained largely in terms of changes in the activity of individual molecules and their interactions. To ultimately understand how biochemistry is related to the physical nature of tissue patterns, we have focused on the cellular mechanism that accounts for the spatial differentials of cell behavior, for example, growth versus quiescence between neighboring cells. Such spatial heterogeneity of cell fates drives tissue patterns formation, such as the branching capillary networks of the vascular system. Our work has revealed the importance of cell adhesion to extracellular matrix (ECM), mechanical forces, and associated changes in cell shape for control of cell fates (Huang and Ingber, 1999). Local alterations in ECM mechanics and tension-dependent changes in cell shape determine the cell's fate with respect to proliferation, differentiation, movement, contractility, and apoptosis in response to soluble hormones and cytokines present in the tissue. For example, as cell spreading on the matrix is progressively inhibited by culturing cells on microfabricated adhesive islands of decreasing area, the cells will proliferate (when spread), shut off growth and differentiate (when spreading is partially inhibited), or undergo apoptosis (when fully retracted and round), even in the presence of attachment to the matrix and of saturating concentrations of growth factors. Similar observations were made in various cell types, including fibroblasts, capillary endothelial cells, vascular smooth muscle cells, and primary liver epithelial cells (Ingber and Folkman, 1989; Singhvi *et al*., 1994; Chen *et al*., 1997; Huang *et al*., 1998; Parker *et al*., 2002; Polte *et al*., 2004). These findings have changed the paradigm in cell-growth regulation and developmental control by placing molecular signaling cascades in the context of the structural and mechanical complexity of living tissues.

2.1. The tensegrity model

Given our finding that mechanical distortion of cells (i.e., global changes in cell shape) plays a central role in cell fate switching during development, a major focus in our laboratory has been to uncover the principles governing how cells assemble and rearrange macromolecules to control their shape, and how mechanical forces impact cellular biochemistry and gene expression via cell distortion.

Our approach to understand how multiple molecular filaments collectively control the mechanical stability of the cytoskeleton – the molecular framework that gives the cell its shape – is based on cellular tensegrity theory (Ingber, 1998; Ingber, 2003a). Tensegrity is a building principle that was first described by the architect R. Buckminster Fuller and first visualized by the sculptor Kenneth Snelson. Fuller defines tensegrity systems as structures that stabilize their shape by continuous tension or "tensional integrity" rather than by continuous compression (e.g., as used in a stone arch). Tensegrity systems are composed of a tensed network of structural members that are stabilized in space because they are balanced by a subset of other members that resist being compressed. It is this preexisting tensile stress (prestress) or isometric tension within a tensegrity network that holds its joints in a stable position, and governs how the whole system of interconnected members responds when mechanically stressed. Our bodies provide a simple example of a tensegrity structure: our bones act like struts to resist the pull of tensile muscles, tendons, and ligaments, and the shape stability (stiffness) of our bodies varies depending on the tone (prestress) in our muscles.

The cellular tensegrity model proposes that the whole cell is a structural hierarchy of molecules that is organized as a prestressed tensegrity structure (Ingber, 2003a). In cells, tensional forces are borne by cytoskeletal microfilaments and intermediate filaments, and these forces are balanced by interconnected structural elements that resist compression, most notably internal microtubule struts and ECM adhesions. However, individual filaments can have dual functions and hence bear either tension or compression in different structural contexts or at different size scales (e.g., contractile microfilaments generate tension, whereas actin microfilament bundles that are rigidified by cross-links bear compression in filopodia). The tensional prestress that stabilizes the whole cell is generated actively by the contractile actomyosin apparatus. Additional passive contributions to this prestress come from cell distension through adhesions to the ECM and other cells, osmotic forces, and forces exerted by filament polymerization. Furthermore, intermediate filaments that interconnect at many points along microtubules, microfilaments, and the nuclear surface as well as the highly elastic, cortical cytoskeletal (actin-spectrin-ankyrin) network directly beneath the plasma membrane provide additional stiffness. The entire integrated cytoskeleton is then permeated by a viscous cytosol and enclosed by a differentially permeable surface membrane.

Importantly a theoretical formulation of the cellular tensegrity model starting from first mechanistic principles was developed by Dimitrije Stamenovic working with our group and by others (Stamenovic and Ingber, 2002; Ingber, 2003a). In this quantitative model of the cell as a mechanical system, actin microfilaments, and intermediate filaments carry the prestress that is balanced internally by microtubules and externally by focal adhesions to the ECM substrate. Work on variously shaped

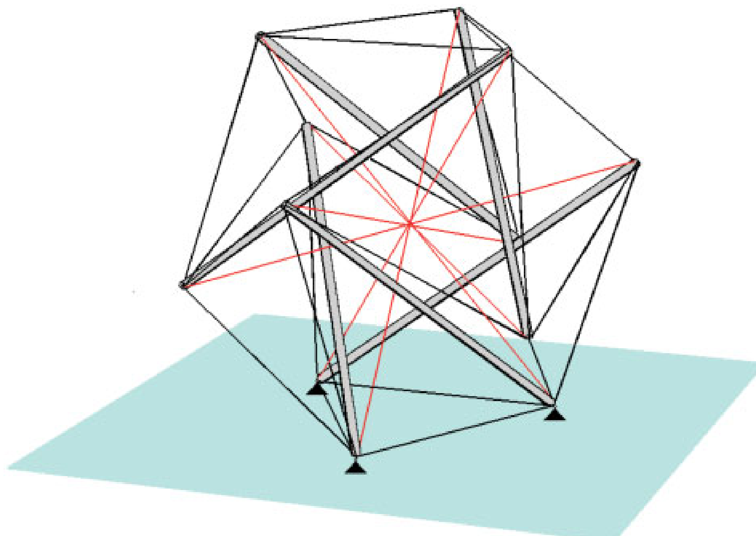

Figure 1 A spherical tensegrity structure used to generate a computational tensegrity model of the cell. The thin tendons represent microfilaments (black lines) and radial intermediate filaments (red lines) in the cytoskeleton; the thick gray struts indicate microtubules. Anchoring points to the substrate (blue) are indicated by the black triangles

models revealed that even the simplest prestressed tensegrity structure embodies the key mechanical properties of all members of this tensegrity class. Thus, for simplicity, we used a symmetrical cell model in which the tensed filaments are represented by 24 cables and the microtubules by 6 struts organized as shown in the structure in Figure 1. The cytoskeleton and substrate together were assumed to form a self-equilibrated, stable mechanical system; the prestress carried by the cables was balanced by the compression of the struts.

A microstructural analysis of this model using the principle of virtual work led to two a priori predictions relating to emergent mechanical behaviors of the entire, integrated, cell-wide, cytoskeletal system: (1) the stiffness of the model (or cell) will increase as the prestress (*preexisting* tensile stress) is raised and (2) at any given prestress, stiffness will increase linearly with increasing stretching force (*applied* stress). The former is consistent with what we know about how muscle tone alters the stiffness of our bodies and it closely matches data from experiments with living cells (Wang *et al*., 2002; Stamenovic *et al*., 2002a, 2003). The latter meshes nicely with the mechanical measurements of stick-and-string tensegrity models, cultured cells, and whole living tissues, although it can be explained by other models also. This mathematical approach strongly supports the idea that architecture and prestress in the cytoskeleton are key to a cell's emergent shape robustness.

Largely through the work of Stamenovic and coworkers, this oversimplified micromechanical model continues to be progressively modified and strengthened over time. A more recent formulation of the model includes, for example, semiflexible struts analogous to microtubules, rather than rigid compression struts,

and incorporates values for critical features of the individual cytoskeletal filaments (e.g., volume fraction, bending stiffness, and cable stiffness) from the literature (Coughlin and Stamenovic, 1997; Stamenovic and Coughlin, 1999). This more refined model is qualitatively and quantitatively superior to the one that contains rigid struts. Another formulation of the tensegrity model that includes intermediate filaments as tension cables that link the cytoskeletal lattice and surface membrane to the cell center (Wang and Stamenovic, 2000) was able to explain mechanical properties of cells lacking the intermediate filament vimentin. All these tensegrity models yield elastic moduli (stiffness) quantitatively similar to those of cultured adherent cells (Stamenovic and Coughlin, 1999, 2000) when measured through cell surface receptors that link to the internal cytoskeleton (Stamenovic and Coughlin, 2003). Although the current formulation of the tensegrity theory relies on a highly simplified architecture (6 struts and 24 cables), it nevertheless effectively predicts many *static* mechanical behaviors of living mammalian cells. Most critically, the a priori prediction of the tensegrity model that cell stiffness will increase in proportion with the prestress has been confirmed in various experimental studies (Wang *et al*., 2002; Stamenovic *et al*., 2002a, 2003).

Interestingly, recent studies have revealed that the *dynamic* mechanical behavior of mammalian cells depends on generic system properties, as indicated by a spectrum of time constants when the cells are stressed over a wide range of force application frequencies (Fabry *et al*., 2001). This work suggests that these dynamic behaviors reflect an emergent property of the cell or cytoskeleton that is observable only at some higher system level of molecular interaction. It is not consistent with the notion of a single type of cytoskeletal filament or molecular interaction (e.g., actin cross-linking) being responsible for cell dynamic behavior. It is also not consistent with standard ad hoc models of cell mechanics that assume the elastic and frictional behaviors of the cell originate from two distinct compartments (the elastic cortex and the viscous cytoplasm). Importantly, computer simulations suggest that dynamic mechanical behaviors exhibited by living cells, including the dependence of both their elastic and frictional moduli on prestress (Wang *et al*., 2001; Stamenovic *et al*., 2002a) may also be explained by their use of tensegrity (Canadas *et al*., 2002; Sultan *et al*., 2004). In other words, tensegrity could provide a common structural basis for both the elastic and viscous behaviors of living cells.

In summary, the work on tensegrity revealed that great insight into cellular behavior due to molecular interactions could be gained by viewing the system as a whole and working from the "top-down" starting with system-level mechanical properties. Specifically, we found that when trying to understand collective mechanical behavior within supramolecular assemblies, higher-order architecture and physical forces also must be considered. This work also revealed how robust behaviors, such as persistence, mechanical adaptability, and shape stability, can be generated using "sloppy" parts (e.g., flexible molecular filaments): since the system properties are "emergent", they do not put very high constraints on the precision of individual component parts and their rules of assembly (Carlson and Doyle, 2002). Thus, tensegrity may represent the "hardware" behind living systems.

3. Attractors in information networks

But what about the software? This leads us to the problem of how structural networks affect information processing networks at the level of the whole cell where tensegrity and the cytoskeleton seem to exert their effects on cell shape and on signal integration. Experiments show that while individual cells in the tissue may receive multiple simultaneous inputs, they are able to rapidly integrate these signals so as to produce just one of a few possible outputs, or cell fate programs (e.g., proliferation, quiescence, differentiation, apoptosis). Furthermore, as described above, cells are able to respond to mechanical cues (e.g., cell shape distortion) with the same behavioral repertoire as they do in response to signals carried by specific molecular messengers, such as hormones or growth factors. The finding that mechanical or geometrical factors that are devoid of the molecular information carried by soluble ligands that bind to specific cell receptors can regulate the exact same biochemical machinery (e.g., cell cycle G1/S transition or apoptosis) as do the specific soluble factors raises a fundamental question: how can a gradual change in a physical control parameter over a broad continuum, such as cell shape (distortion from round to spread), be translated into one of a few discrete and mutually exclusive cellular programs?

Signal transduction, the biochemical process of converting an external molecular signal into a cellular effect, has historically been viewed in terms of "signaling pathways" that lead from a specific input to a particular outcome (*see* Article 108, **Functional networks in mammalian cells**, Volume 6). However, information processing in cells appears to be "distributed": Different stimuli can elicit the same behavior, whereas the same stimulus can generate different responses, depending on the cellular context, including the activity of other regulatory proteins and the physical state of the cell (Huang and Ingber, 2000). The apparent lack of hard-wired, point-to-point, function-specific pathways and the high prevalence of cross-talk between canonical signaling cascades are best documented in signal transduction of cytokines (Kerr *et al*., 2003). DNA microarray analysis now confirms that engaged cytokine receptors induce thousands of genes that can overlap to a great extent (Fambrough *et al*., 1999; Iyer *et al*., 1999; Tamayo *et al*., 1999). Yet, despite this apparent lack of pathway specificity, receptor ligands reliably produce a concerted biological effect, such as proliferation, differentiation, or apoptosis. Thus, equating a molecular signaling cascade with a logical chain of causation may be too simplistic to explain how cells process environmental signals and make discrete cell fate decisions.

It has become evident that signal transduction and gene regulatory pathways form a single, large, connected genome-scale network that spans virtually across the cell's entire regulatory machinery (Marcotte, 2001; Bray, 2003; Huang, 2004). How then can discrete cell phenotypes, such as cell fates, emerge from such genome-wide molecular networks? More generally, a long-standing question in physics has been: Can such large, apparently irregular, that is, "complex" networks produce global, coherent patterns of gene and protein activation – the prerequisite for expression of discrete behaviors at the whole-cell level? While the detailed "wiring diagram" of such molecular information processing networks of the mammalian genome remains largely unknown (*see* Article 110, **Reverse engineering gene regulatory**

networks, Volume 6), early computer models of the dynamics of statistical ensembles of large, generic networks of interacting genes (Kauffman, 1993) have revealed that, for a subset of types of network architectures, "ordered" rather than "chaotic" behavior can arise, in that only a few stable states spontaneously emerge as a result of the global constraints imposed by the regulatory interactions (Kauffman, 1993; Fox and Hill, 2001; Aldana and Cluzel, 2003; Huang, 2004). Importantly, this subset of network architectures that exhibit ordered behavior encompasses those found in nature in lower organisms where gene or protein network topology has been elucidated (Huang, 2004). In such networks with ordered behavior, most states of the network (defined by the configuration of activity of all molecules of the network) are unstable because the respective configuration of gene or protein activation is incompatible with their regulatory relationships: for instance, mutually inhibitory genes cannot be active at the same time. As a consequence, most network states are "attracted" to the few stable network states, known as the "attractor" states, which are stable with respect to the activity status of all the genes of the network, and hence are said to be "high-dimensional". Such attractor states define the activity configuration of genes across the network that complies with the regulatory interactions (see Figure 2 for details). The central idea then is that a cell fate, or more generally, any distinct, stable phenotypic state, is a high-dimensional attractor state in terms of network dynamics (Kauffman, 1993; Huang, 2002). This is essentially an extension to the genomic scale of the old idea that cell differentiation is due to a bistable switch in a gene circuit containing a self-activating gene or protein (Delbrück, 1949; Thomas, 1998)

Since attractors in gene regulatory networks are akin to energy potential wells in some abstract sense, one can think of all the possible states of a network's dynamic behavior, the so-called state space, as constituting a "potential landscape". Then a marble that represents a network state at a given time point will roll down into the valleys or pits to the bottom that would represent the stable attractor states (Figure 2). The movement (change of network state) is driven by the execution of the regulatory interactions. Upon small perturbations (change in activity status of few individual genes), the marble will generally remain within its local neighborhood and roll back down into the same valley; an attractor state is therefore robust to small perturbations in many directions (=with respect to many genes). In response to a larger perturbation, typically involving large sets of genes, however, the marble could traverse a mountainous peak in the landscape and irrevocably be committed to rolling down the other side of the hill (driven by the regulatory interactions in the network) until it reaches another stable attractor in a neighboring valley. In the case of the cell, this corresponds to a cell fate switch that would cause it to take on a different, stable gene activation configuration and thus, exhibit a different stable phenotype.

The "attractor landscape" schematically captures the network's entire behavioral repertoire. Its structure is determined by the genomic gene and protein regulatory network hard-wired in the genome sequence that encodes protein structures and promoters motifs, and hence determines which molecules interact with which one and in what modality. The attractor landscape may be what Waddington had in mind when he proposed in the 1940s, not knowing about gene networks, the metaphor of an "epigenetic landscape" (Figure 3) to explain the discreteness and stability of

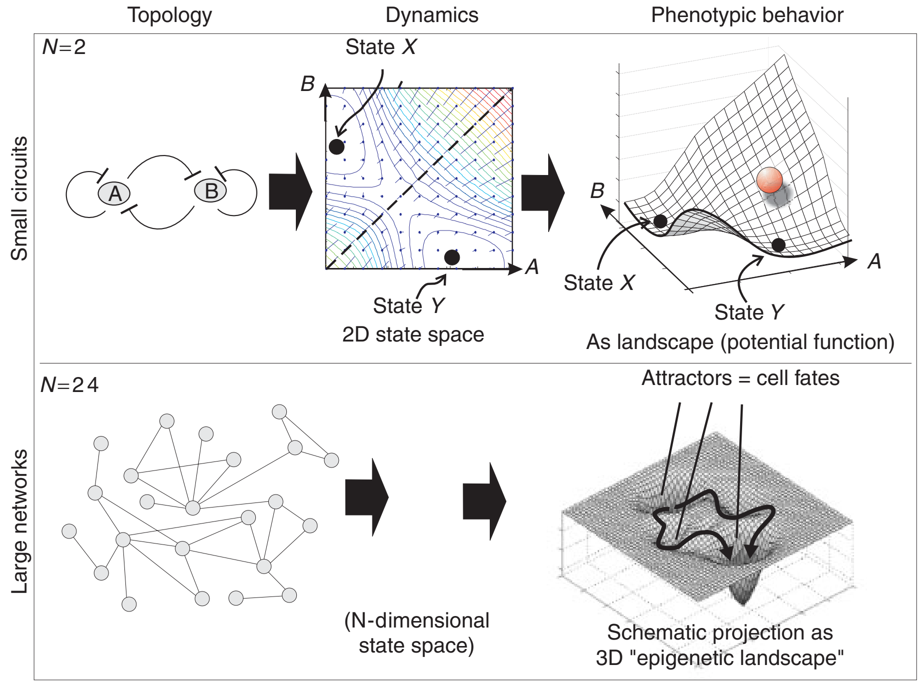

Figure 2 From network topology to dynamics, illustrated for small circuits and large network. Top panel: Small circuit (signaling module) toy model consisting of two proteins, A and B, which are mutually inhibitory (via sigmoidial functions), and promote their own (first order) decay. For a wide range of kinetic parameters, this circuit topology gives rise to bistability. Middle panel shows a phase plane (two-dimensional state space) that represents the dynamics as a vector field. Each dot represents a state $S(t) = [x_A(t), x_B(t)]$ of the circuit at time t, defined by the expression or activity values $x(t)$ of the two nodes, A and B (see text). The ticks emanating from each dot points to the direction in state space in which that respective state will move in the next time unit to comply with the interactions (i.e., systems equations) of the circuit. Contour lines help visualize the landscape character that arises from the dynamics at each point. There are two stable states, X and Y (black dots), to which the ticks point. The dashed diagonal represents the separatrix, the border line between the two basins of attraction. The right panel illustrates the structure of the state space after numerical integration of the vector field from an arbitrary starting point in x and y directions. Although the vector field in this case is not integrable, that is, not a gradient field, the graph shows the landscape character and the bistability with states X and Y as "potential wells" (attractors) and unstable regions in-between. Bottom panel: Analogous illustration of topology and dynamics, but for a larger network ($N = 24$). Now the state space is N-dimensional, containing all the network states, defined by $S(t) = [\, x_1(t), x_2(t), \ldots, x_N(t)\,]$ and cannot be drawn; however, again it can be schematically thought of as some sort of a landscape in which the pits represent (high-dimensional) attractor states (right panel). In this projection, every point in the xy-plane represents a (high-dimensional) network state $S(t)$ arranged so as to generate the landscape, where the vertical axis would represent some "state change potential" value reflecting the "dissimilarity" of the state S_{xy} at position (x,y) to that of the attractor state that it will eventually reach. Each attractor state corresponds to a distinct phenotypic cell state, or a cell fate. The landscape can be thought of as the formal and molecular equivalent of Waddington's "epigenetic landscape" (see Figure 3)

cell fates in development (Waddington, 1956). The attractor landscape metaphor naturally explains systems features of cell fate switching behavior discussed earlier: the existence of discrete specialized cellular programs (cell fates), the all-or-none switch between them, and their mutual exclusivity. It also makes plausible why

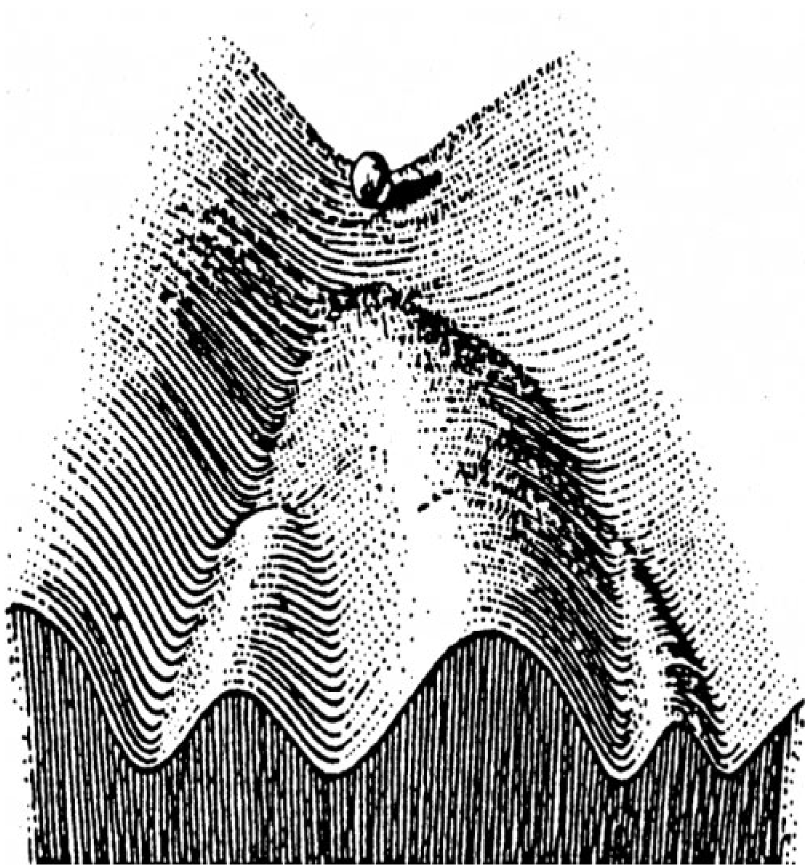

Figure 3 "Epigenetic landscape". A metaphor proposed by Waddington in the 1940s to explain discreteness and stability of cell fates during embryonic development (Reproduced by permission from C. Waddington, (1957), *The Strategy of the Genes*. © Allen and Unwin)

many unrelated signals, including those devoid of molecular specificity can lead to the same cell fate.

Recent experimental work from our laboratory using dynamic gene expression profiling of human promyelocytic HL60 cells that undergo differentiation into neutrophils in response to two distinct stimuli, either a specific (retinoic acid) or a nonspecific (dimethylsulfoxide) agent, provides direct support for the attractor hypothesis. A necessary signature of a transition into a high-dimensional attractor is the convergence of genome-scale gene expression profiles from different perturbed network states as the cell assumes the new phenotypic state (Figure 2, bottom right). Indeed, the mature neutrophil differentiated state in HL60 cells was approached from two different directions in the epigenetic landscape: starting from identical network states, defined by a gene expression profile over ~3000 genes (correlation coefficient $r = 1$), in response to these two distinct agents, the cells visited globally distinct states (profiles) ($r = 0.2$) before being "attracted" to the common one specific for the neutrophils ($r = 0.9$). In terms of individual genes, this

means that differentiation can take alternative paths, that is, genes are turned on and off differently in these two alternative neutrophil differentiation processes. This observation defies the traditional notion of unique, specific, and dedicated "differentiation pathways".

An important corollary of this alternative paradigm of cellular signaling is that, due to the inherent stability of a high-dimensional attractor state, a change in a large set of genes is necessary for a transition from one stable state to another (e.g., switch from proliferation to differentiation) (Huang, 2002). This could explain the pleiotropy and promiscuity in signal transduction pathways that may have been wired by evolution precisely to trigger transitions between different attractor states.

Another fundamental consequence of the concept of a high-dimensional attractor landscape hard-wired in the genome is that it provides a deterministic guiding structure, so to speak a stage on which the inherently noisy molecular processes of regulated gene expression take place (Paulsson, 2004). The stability of high-dimensional attractors ensures that the stochastic fluctuations in the levels of expression and activation of multiple interacting proteins will not affect cell phenotype. Thus, a stable phenotype (e.g., a quiescence state) of an apparently homogeneous cell population may actually represent a "swarm" of points rather than a single point at the bottom of an attractor. Accordingly, signal transduction then may be viewed as a process that orchestrates these random fluctuations in the activity of thousands of individual genes so that their joint probability of activation may produce an "outlier" cell in the swarm that would jump over a crest and roll down to another attractor (Figure 4). Since the attractor requires that

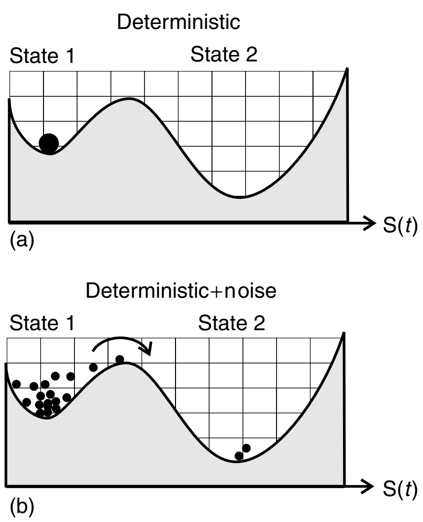

Figure 4 Effect of noise on a network with two attractor states. Schematic illustration of how the attractor landscape controls and exploits molecular noise. Every dot corresponds to a network state, defined by its position in the horizontal axis. (a) A situation without noise. (b) Noise is added to the same system. Noise can "kick" the system out of one state and force it to transition to another stable state. Because of the attractors, a specific transition (from state 1 to state 2) can occur following a nonspecific (noisy) perturbation

multiple genes be regulated to produce an attractor switch, a combinatorial scheme in which the fluctuations in the individual genes are biased by the external signal would allow the fine-tuning of the "macroscopic" cell fate transition probability. In fact, the stochastic nature of cell lineage commitment in stem cells as well as many forms of cell fate regulation appears to be due to the combined effect of deterministic, instructive external regulators and intrinsic probabilistic, digital events (Enver *et al*., 1998; Hume, 2000; Lahav *et al*., 2004).

4. Integration of structural and information processing networks

If system-level behavior of a whole cell is a transition between robust, high-dimensional attractor states of the regulatory network, then the requirement for specific details of input signals can be relaxed. This provides the evolvability necessary for cells to evolve the capability to harness environmental cues that lack molecular specificity, such as physical forces and mechanical distortion, to serve as signals that can cause a particular cell fate transition and the associated highly concerted changes in gene expression.

The precise molecular mechanism by which a physical change in a cell is transduced into a biochemical signal is not fully understood. However, what is now well documented is that the actin cytoskeleton acts as a scaffold for the assembly of many signaling pathway protein complexes (Geiger and Bershadsky, 2001) and that a change in the actin network architecture (or prestress) can affect the activity of large arrays of signaling pathways. In fact, many of the biochemical events that mediate cell metabolism and signal transduction require solid-state biochemistry: cellular enzymes and substrates that mediate these biochemical reactions are immobilized on insoluble molecular scaffolds within the cytoskeleton and nuclear matrix (Ingber, 2003a). Mechanical forces are transmitted across cell surface adhesion receptors, such as integrins, that mechanically couple ECM scaffolds to the same internal cytoskeletal scaffolds (Wang *et al*., 1993) and are thought to be converted into chemical and electrical signals through stress-dependent distortion of molecules that associate with load-bearing elements of the cytoskeleton (Ingber, 2003a). In this manner, physical distortion of the structural network in cells may affect a large set of signaling pathways (Alenghat and Ingber, 2002). Yet, because of the existence of stable attractors in the information-processing network, physical perturbations and associated pleiotropic biochemical signals would be channeled down a valley in the epigenetic landscape, and hence automatically orchestrated to trigger a specific cellular program. This is consistent with the widely seen ability of cell shape distortion to influence cell fates as discussed earlier.

The integration of the global mechanical state of a cell, as predicted by the tensegrity model, with the regulation of cell fates is key to development and tissue homeostasis because it governs the spatial organization of the expression of distinct cellular phenotype so as to comply with the macromechanical demands (stretching or compression of tissue) within an organism. A prosaic example for this sculpting and molding of tissues guided by physical reality is wound healing. When

cells are lost from an epithelium due to injury, cells surrounding the wound will spread, move to fill the space, and divide until the initial state of cell compaction (compression) is restored; then proliferation shuts off. Similarly, during embryonic development cells, in regions of tissues that experience higher levels of deformation also often exhibit higher proliferation rates (reviewed in Huang and Ingber, 1999; Ingber, 2003b), thus balancing cell proliferation with macroscopic need.

5. Conclusion

In this chapter, we presented two complex system aspects of cells that elude explanation by the molecular characterization of individual components or pathways: the cell *as a physical entity* with mechanical properties and the cell's *global information processing behavior* that mediates cell fate decisions. We showed how the concept of "network" in the broadest sense facilitates the bridging of the gap between molecules and system-level behaviors. It is important to note that cytoskeletal and regulatory networks belong to entirely different classes of objects: the former is a concrete physical scaffold made of individual proteins, while the latter is an abstract wiring diagram between symbols representing molecular species. Nevertheless, both network concepts help us understand how a robust, system-level feature emerges from rule-governed interactions between molecules. Tensegrity structures explain the mechanical properties of a whole cell, and attractor states explain cell fate switching. Such a conceptual understanding does, of course, not obviate the need for our continuing efforts to achieve a comprehensive characterization of all the molecular constituents and processes in the cell. But it emphasizes the importance of complementing the pathway-centered approach that currently dominates Systems Biology with top-down approaches that embrace the actual system properties. Only in this manner will it be possible for us to understand how and why the whole is more than the sum of its parts once we have catalogued all the molecular components.

Specialist Review

Systems biology of the heart

Denis Noble
University Laboratory of Physiology, Oxford, UK

1. Introduction

Systems biology of the heart has focused on understanding cellular and multicellular function in terms of the interactions between proteins forming channels, transporters, receptors, contractile elements, sequestration structures, and buffers. It is a good example of the need for reduction and integration to complement each other. Without identifying the elements, their coding genes, molecular structure, and their reactions there would be no basis on which to build models; equally, without modeling the interactions of these components there would be no understanding of overall function. The first successful example of this approach came when Hodgkin and Huxley (1952) published their equations for the squid giant axon. This was the first model to use mathematical reconstruction of ion channel transport and gating, rather than abstract equations and it correctly predicted the shape of the action potential, the impedance changes and the conduction velocity. It was a brilliant demonstration of the need for biological modeling to respect the details of experimental results.

Theoretical biology has only rarely been as successful as this. The squid axon is a relatively simple nervous mechanism. Most nerve cells are much more complex, and so are cardiac cells, with the added complexity of electromechanical coupling and mechanoelectric feedback (Noble *et al*., 1998). Modeling the heart has therefore required many more rounds of iteration between experimental and modeling work.

Even in the physical sciences, modeling has usually been an iterative process of interaction between mathematics and experimentation, involving successive approximations toward predictive capability. The iterative process generates insights on the way, even when models are wrong or incomplete. In fact, the mistakes can be as illuminating as the successes (Noble, 2002b). Models of complex biological systems should be judged as much by the insights they have given, as by their predictive power.

2. Potassium channels: energy conservation and the fragility of repolarization

The first integrative questions to be resolved were fundamental to cardiac electrophysiology. Compared to nerve, where the total duration is only a millisecond

or two, the cardiac action potential is exceedingly long. Hundreds of milliseconds are required for repolarization to occur. And when the resting potential has been restored, it is not necessarily stable. In pacemaker regions, like the SA node, the AV node, and the Purkinje fibers, it immediately starts to depolarize again to generate spontaneous rhythm.

What is responsible for these differences? The answer lies primarily in the nature of the potassium channels in cardiac cells. The first experimental results (Hutter and Noble, 1960; Carmeliet, 1961) showed the existence of two kinds: the inward rectifier, i_{K1}, now known to be coded by Kir2.x, and delayed rectifier i_K. The delayed rectifier was later shown to be generated by multiple components (Noble and Tsien, 1969; Sanguinetti and Jurkiewicz, 1990; Zeng *et al*., 1995), including i_{Kr}, coded by hERG and MinK, and i_{Ks}. We now know that there are many other K^+ channels whose expression levels vary with spatial location (Antzelevitch *et al*., 2001). These include i_{to}, which shapes the early phases of the action potential.

The discovery of the inward rectifier was a surprise. On depolarization, it closes so that the conductance changes in precisely the opposite direction to that of the potassium channel in squid giant axon, and it was natural to ask the question whether this could account for the long-lasting nature of the cardiac action potential. The model incorporating this mechanism (Noble, 1962) showed unambiguously that it could. In fact, it is a major energy-saving device since, by reducing the membrane permeability, very small inward currents (generated by sodium and calcium ions) suffice to maintain a long plateau of depolarization. The energy cost of a long action potential generated in this way is an order of magnitude less than it would otherwise be. The 1962 model also correctly attributed repolarization to i_K, and identified its decay as an important contribution to pacemaker activity.

Evolution involves a play-off between competing factors: energy conservation and safety being two of them. Engineers are familiar with this concept in the context of constructing aircraft, bridges, spacecraft, elevators, and a host of other technologies. Evolution approaches these competing factors in similar ways (Diamond, 1993). Energy conservation may have been one reason for the evolution of channels like i_{K1}, but in the play-off there was a very severe price. What this model and all later models showed is that repolarization becomes a much more fragile process. Very small current changes can disturb and even prevent it. Moreover, the channel mainly responsible, i_{Kr}, is one of the most promiscuous receptors known to pharmacology. This channel protein or the G-coupled proteins controlling it, interact with a large range of compounds, including drugs as diverse as antibiotics, antihistaminics, anticancer drugs, antihypertension drugs, and so on, the list is almost endless, many of which interfere with repolarization in a way that generates potentially fatal arrhythmias. A major challenge for systems modeling now is whether it can help overcome these problems (Muzikant and Penland, 2000).

While the 1962 model successfully represented the roles of i_{K1} and i_K, it completely lacked calcium fluxes, and its representation of pacemaker activity was far too simple. There are many other mechanisms involved, including the hyperpolarizing-activated current i_f (DiFrancesco and Noble, 1985; DiFrancesco, 1993) and various sodium and calcium channels (Irisawa *et al*., 1993). Modeling of pacemaker activity is currently a hot topic, with the roles of a number of ion transporters being reassessed (Rigg and Terrar, 1996; Cho *et al*., 2003) and

variations in expression levels incorporated (Zhang *et al*., 2000). A major new focus of this work is the mouse, which is of great importance in correlating genetic information with electrophysiology (Liu *et al*., 2003; Demolombe *et al*., 2004) and for interpreting the effects of genetic modifications (Noble, 2002d; Papadatos *et al*., 2004). Without a systems biological approach, it would be impossible to understand a process as multifactorial as cardiac rhythm generation. This is true not only of normal pacemaker activity but also of abnormal arrhythmic mechanisms.

3. Calcium balance: calcium channels, sodium–calcium exchange, sarcoplasmic reticulum

Harald Reuter first discovered calcium channels in the heart (Reuter, 1967), and discovered the sodium–calcium exchanger (Reuter and Seitz, 1969). Later, Alex Fabiato first demonstrated calcium-induced release of calcium from the sarcoplasmic reticulum (Fabiato, 1983).

The next major role for systems biological modeling was to integrate these three processes into the cellular web of interactions. Calcium currents were incorporated into a Purkinje fiber model by McAllister *et al*. (1975), and into the first ventricular cell model by Beeler and Reuter (1977), but the first integrative models that addressed the key questions of calcium balance were those developed with DiFrancesco (DiFrancesco and Noble, 1985) and Hilgemann (Hilgemann and Noble, 1987). These became the generic models from which all the modern models of excitation-contraction coupling derive (Luo and Rudy, 1994a,b; Jafri *et al*., 1998; Noble *et al*., 1998; Winslow *et al*., 1999; Winslow *et al*., 2000). The Hilgemann–Noble model addressed a number of important questions concerning calcium balance:

1. How quickly is calcium balance achieved? Net calcium efflux is established as soon as 20 ms after the beginning of the action potential (Hilgemann, 1986), which was considered to be surprisingly soon. In the model, this was achieved by calcium activation of efflux via the Na–Ca exchanger, thus revealing the time course of one of the important functions of this transporter in the heart.
2. Since the exchanger is electrogenic, where was the current that this would generate and did it correspond to the quantity of calcium that the exchanger needed to pump? Mitchell *et al*. (1984) provided the first experimental evidence that the action potential plateau is maintained by sodium–calcium exchange current. The Hilgemann–Noble model showed that this is precisely what one would expect, both qualitatively and quantitatively. Subsequent experimental and modeling work has fully confirmed this conclusion (Egan *et al*., 1989; LeGuennec and Noble, 1994; Eisner *et al*., 2000; Bers, 2001).
3. Could a model of the sarcoplasmic reticulum SR that reproduced the major features of Fabiato's experiments be incorporated? The model followed as much of the Fabiato data as possible, but while broadly consistent with the Fabiato work it could not be based on that alone. Fabiato's experiments were heroic but they were done on skinned fibers, which removes many of the relevant

mechanisms. It is an important function of systems biological models to reveal when experimental data needs extending.

4. Were the quantities of calcium, free and bound, at each stage of the cycle consistent with the properties of the cytosol buffers? The great majority of the cytosol calcium is bound so that, although large calcium fluxes are involved, the free calcium transients are much smaller, as they are experimentally.

The major deficiency of this model was that it could not account for graded release of calcium from the SR, or for the phenomenon of calcium sparks. Much more complex models, incorporating finer detail of the excitation–contraction process, including the communication between L-type calcium channels and the SR calcium release channels, are required to achieve this (Jafri *et al*., 1998; Rice *et al*., 1999; Winslow *et al*., 2000; Greenstein and Winslow, 2002; Hinch, 2004).

4. Modeling disease states

An important criterion for success in systems biology is the ability to account for disease states. In this section, I will show that modeling of the heart has begun to do this.

4.1. Genetic mutations

Connecting genetics to physiological function at cellular and other levels is an exciting new development in which systems biological simulations are helping to unravel complex behavior resulting from simple changes at the genetic level. Clancy and Rudy (1999) have revealed the arrhythmogenic effects of a mutation that affects sodium channel inactivation and is associated with a congenital form of the long-QT syndrome, LQT3. Long-QT refers to prolongation of the electrocardiogram interval between excitation of the ventricles (Q) and their repolarization (T), a phenomenon that can indicate life-threatening arrhythmias. The simulations show that the mutant channel generates a persistent inward sodium current during the action potential plateau, and at long cycle lengths this generates an early after-depolarization so delaying repolarization and prolonging the QT interval. Noble and Noble (2000) have shown similar consequences of shifting the voltage-dependence of sodium channel inactivation. This mimics part of the experimental effect of a missense mutation underlying the Brugada syndrome, an inherited condition in which sudden fatal ventricular fibrillation can occur in people who show no other manifestation of heart disease.

4.2. Congestive heart failure

The ability to track multiple changes in gene expression levels using cDNA arrays, real-time PCR, and other methods has revolutionized the range and quantity of data available on disease states. A major problem, however, is to distinguish those

changes that are primary from secondary changes attributable to remodeling in response to the disease state. Systems biology can help in this distinction since it can identify those changes that explain the disease effect, such as cardiac arrhythmia. An excellent example of this approach is the modeling of congestive heart failure. Experimental data shows that i_{to} and i_{K1} are downregulated, leading to a prolongation of the action potential, while the SR calcium pump, SERCA, is also downregulated leading to a reduction and slowing of the intracellular calcium transient. Sodium–calcium exchange is upregulated, which may be a secondary response to the other changes in calcium handling. Introducing these changes into cardiac cells models succeeds in reproducing failure of repolarization and multiple reexcitations of the kind that generate major arrhythmia (Winslow *et al*., 1999) and in showing that the major factor involved is the change in calcium balance.

4.3. Ischemia

Ischemia is a multifactorial process, starting with interruption of the blood supply, leading to rundown of metabolites like ATP involved in driving energy-using mechanisms, with consequent changes in ionic concentrations. These processes have been partially modeled (Ch'en *et al*., 1998). Both the metabolic and the ionic changes in turn modulate the activity of channels and transporters. Thus, some potassium channels, $i_{K,ATP}$ are activated by the fall in ATP (Noma, 1983), so shortening the action potential. Extracellular accumulation of potassium ions also contributes to this shortening through changes in i_{K1} and i_{Kr}. Meanwhile, the development of sodium and calcium overload may generate oscillatory changes in intracellular calcium that may initiate ectopic beating. These are the acute changes. Long-term changes create scar tissue that can contribute to determining the pathways for reentrant arrhythmia. Unraveling the ways in which all these processes interact to generate life-threatening arrhythmia is a problem that requires modeling. The interactions are too complex to be understood without quantitative study. However, at present, all the model studies are partial ones, and they have mostly been carried out at the cellular level, though Rudy and his colleagues (Shaw and Rudy, 1997; Wang and Rudy, 2000) have done important studies on one-dimensional multicellular models and an ectopic focus has been simulated in 2D and 3D models (Winslow *et al*., 1993). Computations at the whole organ level have yet to appear. These will be important since reentrant arrhythmia and fibrillation are properties of the whole ventricle.

5. Linking levels: putting cell models into tissue and organ models

Life-threatening arrhythmias depend on molecular and cellular mechanisms but they are fatal because of their actions at the level of the whole organ. Anatomically detailed models of the ventricles, including fiber orientations and sheet structure (Crampin *et al*., 2004), have been used to incorporate the cellular models in an attempt to reconstruct the electrical and mechanical behavior of the whole organ.

These models have been used to reconstruct the spread of the activation wave front, generated largely by the rapidly activated sodium channels and to reconstruct reentrant waves and their breakdown into the multiple wavelets of fibrillation (Bernus *et al*., 2003; Ten Tusscher and Panfilov, 2003; Panfilov and Kerkhof, 2004). These processes are heavily influenced by cardiac ultrastructure, with preferential conduction along the fiber-sheet axes, and the result corresponds well with that obtained from multielectrode recording from dog hearts in situ. Accurate reconstruction of the depolarization wavefront promises to provide reconstruction of the early phases of the ECG to complement work already done on the late phases (Antzelevitch *et al*., 2001) and as the sinus node, atrium and conducting system are incorporated into the whole heart model, we can look forward to the first example of reconstruction of a complete physiological process from the level of protein function right up to routine clinical observation.

The whole ventricular model has been incorporated into a virtual torso (Bradley *et al*., 1997), including the electrical conducting properties of the different tissues, to extend the external field computations to reconstruction of multiple-lead chest and limb recording. Incorporation of biophysically detailed cell models into whole organ models (Noble, 2002a,c; Trayanova *et al*., 2002; Crampin *et al*., 2004) is still at an early stage of development, but it is essential to attempts to understand heart arrhythmias. So also is the extension of modeling to human cells (Nygren *et al*., 1998; Ten Tusscher *et al*., 2003).

Specialist Review

Integrative modeling of the pancreatic β-cell

Arthur Sherman
National Institutes of Health, Bethesda, MD, USA

Richard Bertram
Florida State University, Tallahassee, FL, USA

1. Introduction

Mammalian metabolism is well adapted to switch between carbohydrate and lipid fuels depending on availability. One of the key hormones involved is insulin, which promotes glucose oxidation and fat storage when carbohydrate is abundant. In the developed world, unprecedented affluence has resulted in chronic excess of both nutrients relative to energy expenditure requirements, leading to an epidemic of obesity, hypertension, hyperlipidemia, and heart disease. An integral part of this metabolic syndrome is resistance to the effects of insulin, possibly as a compensation for overnutrition (Unger, 2003). In response, the β-cells of the pancreatic islets of Langerhans oversecrete insulin to maintain plasma glucose within normal ranges. In many cases (currently about 6% of the population of the United States), the β-cells fail to compensate, leading to hyperglycemia (Type II diabetes), further morbidity, and premature death. For these reasons, there has been much interest in understanding how β-cells regulate plasma glucose. This control mechanism centers on complex patterns of oscillation in membrane potential and cytosolic calcium, which are difficult to understand without the aid of mathematical models. Those models are the focus of this review.

2. Schematic model

The β-cell models build on the Hodgkin–Huxley paradigm (Hodgkin and Huxley, 1952), in which the plasma membrane is represented as an RC circuit, with the ion channels providing the resistance and the lipid bilayer providing the capacitance. The great success of such models in explaining the diverse electrical properties of neurons, muscle, and endocrine cells stems from the ability to reduce the electrical apparatus to a simple physical model, which can be represented by a small system of ordinary differential equations. The availability of dynamic readouts (voltage

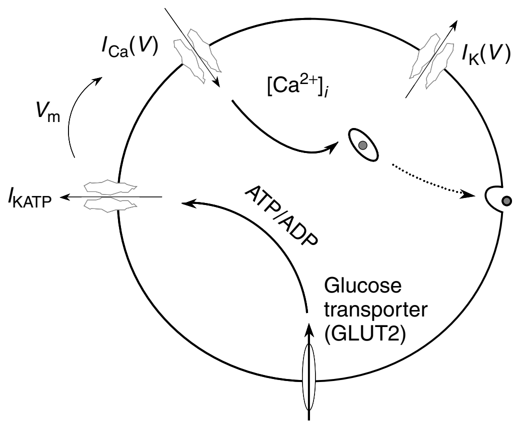

Figure 1 Consensus schematic of β-cell. Glucose triggers depolarization and Ca^{2+} entry, which signals exocytosis of insulin granules

and calcium) with high time resolution has also been crucial. The validity of isolating the electrical module was strikingly demonstrated by transfecting voltage-dependent Na^+ and K^+ channels into nonexcitable Chinese hamster ovary cells, which endowed them with neuron-like action potentials (Hsu *et al*., 1993).

The minimal parts list for the β-cell is shown in Figure 1. The voltage-dependent Ca^{2+} channel conducts Ca^{2+} ions into the cell, which raises the transmembrane voltage, V, whereas the K^+ channel gates efflux of K^+ and restores V to a low level. The temporal interaction of the two channels is sufficient to explain the repetitive spiking observed in β-cells. The Ca^{2+} influx also provides the primary chemical signal to trigger exocytosis of insulin-containing granules. These components are typical of many endocrine cells, but the β-cell needs an additional metabolic module to connect the level of electrical activity to plasma glucose concentration. Metabolism of glucose raises the ratio of ATP to ADP, which closes a third channel, the K(ATP) channel. Thus, in the absence of glucose, β-cells are electrically silent, but they generate Ca^{2+}-dependent action potentials when glucose is elevated.

This is the consensus schematic model for β-cells and is sufficient for understanding many aspects of diabetes pathology and therapy. For example, one of the classes of drugs used to treat Type II diabetes, the sulfonylureas, block K(ATP) channels independent of glucose metabolism and augment insulin secretion (Ashcroft and Rorsman, 1989). Also, recently it has been shown that either a surplus or a deficit of K(ATP) activity can lead to diabetes (Seino and Miki, 2003). In the former case, K(ATP) channels that fail to close in response to glucose result in inadequate secretion of insulin. In the latter case, K(ATP) channels that are always closed independent of glucose result in childhood hyperinsulinism. Some patients who survive this devastating hypoglycemia into adulthood become diabetic, possibly because their β-cells fail from chronic depolarization and exposure to high $[Ca^{2+}]$ (Glaser, 2003).

In both mice (Ashcroft and Rorsman, 1989) and humans (Martin and Soria, 1996), insulin secretion is controlled by oscillations of calcium, which are driven by *bursts* of action potentials with periods ranging from tens of seconds to several

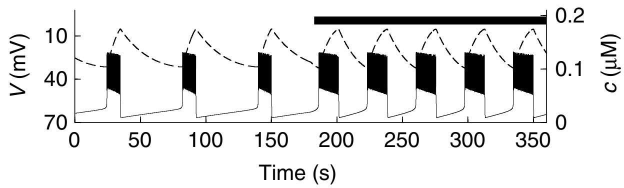

Figure 2 Simulation of glucose step with Chay–Keizer-like model (equations 1–5). Each plateau in voltage (V; solid) is a train of brief spikes. Cytosolic calcium (c; dashed) rises slowly to terminate the bursts and recovers slowly in the silent phase. The black bar indicates period of elevated glucose

minutes (see Figure 2 for an illustration using the model). We want to understand how bursting arises, how it is modulated by glucose and other signals, and how such a broad dynamic range is achieved. Three illustrative models are presented below in a didactic sequence of increasing complexity and explanatory power. Bear in mind that the actual historical development was more complex and subject to alternate interpretations.

3. The Chay–Keizer model

The first widely adopted mathematical model for bursting in β-cells was developed by Chay and Keizer (1983), on the basis of the hypothesis of Atwater and Rojas that the slow dynamics of intracellular free Ca^{2+} are responsible for packaging impulses into bursts (Atwater *et al*., 1980); that is, the sustained high voltage of the *active phase* of each burst would slowly increase cytosolic $[Ca^{2+}]$ (c), which would gradually activate a Ca^{2+}-activated K^+ (K(Ca)) channel until a critical level was reached that would shut the spiking off. In the absence of spiking, c would slowly recover, giving a long *silent phase* (Figure 2).

Chay and Keizer also sought to explain how an increase in plasma glucose modulates the bursts by prolonging the active phases and shortening the silent phases, that is, increasing the *plateau fraction*. They suggested that increased glucose would increase activity of the plasma membrane Ca^{2+}-ATPase (PMCA), slowing the rise of c and accelerating its fall. In keeping with the modular approach, the machinery of metabolism enters only through its effect on the pump rate (black bar, Figure 2).

The equations that correspond to the above scheme and that were used to produce Figure 2 are in outline:

$$\frac{\mathrm{d}V}{\mathrm{d}t} = -\frac{I_{\mathrm{Ca}}(V) + I_{\mathrm{K}}(V,n) + I_{\mathrm{K(Ca)}}(V,c) + I_{\mathrm{K(ATP)}}(V)}{C_{\mathrm{m}}} \tag{1}$$

$$\frac{\mathrm{d}n}{\mathrm{d}t} = \frac{n_\infty(V) - n}{\tau_n} \tag{2}$$

$$\frac{\mathrm{d}c}{\mathrm{d}t} = f_{\mathrm{cyt}} J_{\mathrm{mem}} \tag{3}$$

(The full equations and parameter values are posted at **http://mrb.niddk.nih.gov/sherman**.) The electric circuit is represented by equations (1) and (2) for the membrane potential (V) and the activation level (open probability) of the voltage-dependent K^+ current (n), respectively. Equation 1 is Kirchhoff's law, which balances capacitive current with the four ionic currents, the voltage-dependent Ca^{2+} (I_{Ca}), voltage-dependent K^+ (I_K), Ca^{2+}-dependent K^+ ($I_{K(Ca)}$), and ATP-sensitive K^+ ($I_{K(ATP)}$) currents. Note that in order to obtain spikes, the RC circuit must be elaborated by assuming that the resistive elements (i.e., the ion channels) change their conducting state in response to V. These changes have been measured (Ashcroft and Rorsman, 1989) and incorporated semiquantitatively into the model. For the present, the conductance of $I_{K(ATP)}$ is held constant, unlike the conductances of the other currents, which vary as V or c change in time. Later, we will introduce dependence on glucose through the ATP production rate.

The slow dynamics of c are modeled by simple mass balance, assuming one well-mixed compartment. Influx through Ca^{2+} channels increases c, while efflux through the PMCA decreases it:

$$J_{mem} = -\alpha I_{Ca}(V) - k_{PMCA}c \tag{4}$$

(Note that I_{Ca} is negative by convention, so $-\alpha I_{Ca}$ is positive.) The net flux of Ca^{2+}, J_{mem}, is multiplied by f_{cyt}, the ratio of free to total (free + buffered) Ca^{2+}. f_{cyt} is small here (0.00025), which makes c slow. Calcium responds to the membrane potential through I_{Ca}, and in turn influences the membrane potential through $I_{K(Ca)} = g_{K(Ca)}\omega(V - V_K)$, where the activation variable ω is:

$$\omega = \frac{c^2}{c^2 + K_D^2} \tag{5}$$

A noteworthy feature of the Chay–Keizer model is that the voltage plateau is not explicitly included in the model. It is an emergent property arising from the $V - n$ interactions. This contrasts with an earlier model (Matthews and O'Connor, 1979), which postulated a special plateau current. This made for a more complex and cumbersome model than Chay–Keizer and may have contributed to its later neglect, in spite of its anticipation of many aspects of Chay–Keizer and other later models.

4. The endoplasmic reticulum: A second Ca^{2+} compartment

In addition to accounting for two major known properties of β-cells, the Chay–Keizer model made a prediction that cytosolic Ca^{2+} would oscillate, with a slow rise and fall. When Ca^{2+} was later imaged in β-cells (Valdeolmillos *et al.*, 1989), it was indeed seen to rise and fall, which was not surprising, but the kinetics were not as expected: c rose rapidly at the beginning of the active phase to a plateau and sometimes even fell slightly toward the end of the active phase. The K(Ca) channel hypothesis fell into disfavor, but has been revived, in part because

of the discovery of a candidate K(Ca) channel in β-cells (Goforth *et al*., 2002; Göpel *et al*., 1999), and in part because of an improved model due to Chay (1996), which included a second, internal Ca^{2+} compartment, representing the endoplasmic reticulum (ER).

There are several reasons for including the ER. As a storehouse for Ca^{2+}, it can influence the Ca^{2+} dynamics of both excitable and nonexcitable cells (Berridge, 1997). In islets in particular, releasing Ca^{2+} from the ER by either blockade of the ER Ca^{2+} pump (SERCA) or activation of IP_3 receptors dramatically affects electrical activity, Ca^{2+} oscillations, and secretion (Bertram *et al*., 1995b; Goforth *et al*., 2002; Worley *et al*., 1994).

The ER compartment is incorporated into the model by adding an ER-to-cytosol flux term (J_{ER}) to equation (3) and by adding a differential equation for the free ER Ca^{2+} concentration (c_{ER}). All forms of efflux are subsumed in a leakage pathway (J_{leak}), and influx occurs through SERCA pumps (J_{SERCA}):

$$J_{ER} = J_{leak} - J_{SERCA} \tag{6}$$

We neglect the known nonlinearities of these processes and write $J_{leak} = p_{leak}(c_{ER} - c)$ and $J_{SERCA} = k_{SERCA}c$. The effect of IP_3 can be represented simply by an increase in p_{leak}. The equations for c and c_{ER} are

$$\frac{dc}{dt} = f_{cyt}(J_{mem} + J_{ER}) \tag{7}$$

$$\frac{dc_{ER}}{dt} = -f_{ER}\left(\frac{V_{cyt}}{V_{ER}}\right)J_{ER} \tag{8}$$

where f_{ER} is the ER Ca^{2+} buffering factor, and V_{cyt} and V_{ER} are the cytosolic and ER volumes.

The behavior of the enhanced model is shown in Figure 3. The rapid jump in c at the beginning of each active phase reflects the intrinsic kinetics of cytosolic Ca^{2+}, which have been accelerated compared to Figure 2 by reducing the cytosolic buffer capacity (i.e., increasing f_{cyt} to the more realistic value of 0.01). This rise in c does not alone provide adequate inhibition to terminate the active phase, but as the ER slowly fills, c is pushed up to the necessary critical level. When spiking ceases, c jumps down rapidly and then slowly decays as the ER gives back the Ca^{2+} it took in during the active phase. Thus, like a buffer, the ER slows down c, but because the ER is slow (whereas buffers are fast), c displays two distinct kinetic phases, in agreement with experiments.

The model parameters in Figure 3 are chosen to give an oscillation period comparable to that typically observed in islets (10–60 s). However, if $g_{K(Ca)}$ is increased, the initial jump in c becomes sufficient to terminate an active phase without assistance from c_{ER}, resulting in a period of only a few seconds. (Similar fast bursting can also be obtained by partially emptying the ER. See Figure 4.) Conversely, reducing $g_{K(Ca)}$ (and possibly adjusting k_{PMCA}), produces periods of several minutes, which are also observed in experiments. This broad range of frequencies is possible because the time scale of oscillations is determined by

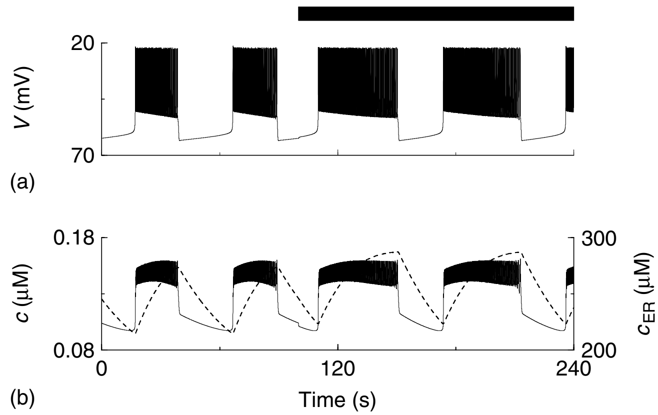

Figure 3 Chay–Keizer model with a slow ER compartment (c_{ER}, dashed). c now has fast and slow components, and increasing PMCA rate now increases both plateau fraction and mean c

mixing the relatively fast c and the relatively slow c_{ER} components. We call this "phantom bursting" because the time scale is not determined by any single process (Bertram and Sherman, 2004).

A comparison of Figures 2 and 3 shows that the ER enhances the model in another way. Whereas both the original Chay–Keizer model and the ER model explain how glucose can raise plateau fraction, in the one-compartment Chay–Keizer model, this does not lead to an increase in the mean level of cytosolic [Ca^{2+}]. In the ER model, in contrast, the approximately square shape of c means that an increase in plateau fraction produces an increase in the average level of c, without any change in the minimum and maximum values, as more time is spent at the higher level relative to the lower level. Note that this occurs in spite of the fact

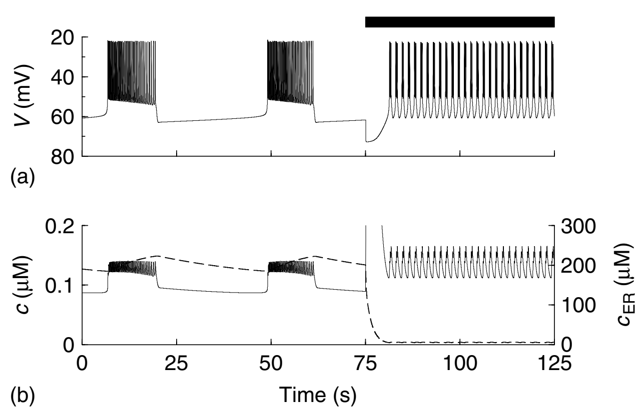

Figure 4 Response of model with ER to acetylcholine (ACh), modeled as a step increase in p_{leak}, throughout period denoted by black bar. Release of Ca^{2+} from ER (b; dashed) gives a transient sharp peak of c (solid; truncated for clarity). Plateau of high c is maintained by an ACh-activated inward current, which drives depolarized, fast bursting (a)

that the rate of pumping Ca^{2+} out of the cell is increased, illustrating that steady state intuitions may not apply when there are oscillations.

As alluded to earlier, inclusion of the ER also allows the model to account for the effects of acetylcholine (ACh) application (Figure 4). In vivo, ACh is released from parasympathetic nerve terminals in the pancreas to stimulate the islets in response to food ingestion (Woods and Porte, 1974). This auxiliary control mechanism raises insulin in anticipation of the coming glucose load and helps limit the rise in plasma glucose. At the cell level, ACh stimulates the production of IP_3, which activates IP_3 receptors on the ER. Here we again collapse an external regulatory module into a change in a parameter of the core electrical/calcium module: the efflux permeability p_{leak} is stepped up 45-fold. This is sufficient to produce the increase in burst frequency seen experimentally. However, in order to capture the rise in V and c that are also seen, we need to add a small depolarizing current ($I_{\mathrm{ACh}} = g_{\mathrm{ACh}}(V - V_{\mathrm{ACh}})$, where $g_{\mathrm{ACh}} = 5$ pS and $V_{\mathrm{ACh}} = 0$) to the V equation. Such a current has now been found (Mears and Zimliki, 2004; Rolland *et al*., 2002). The depolarized bursting and elevation of the cytosolic Ca^{2+} concentration are critical because they contribute to the increase in insulin secretion.

5. Oscillations in glucose metabolism

We now consider the glucose dependence of the K(ATP) channel. If the K(ATP) conductance is assumed to decrease with external glucose concentration, then plateau fraction is modulated similarly to the changes obtained in Figures 1 and 2 by varying PMCA pump rate (not shown). Beyond this, there is some evidence that ATP and ADP concentrations in β-cells vary over time (Ainscow and Rutter, 2002) in a Ca^{2+}-dependent manner (Kennedy *et al*., 2002). This was proposed by Keizer and Magnus (1989), who assumed that the rate of ATP production decreases when cytosolic Ca^{2+} inhibits the mitochondrial membrane potential. Phenomenologically, this can be represented by the following equation for ADP concentration:

$$\frac{\mathrm{d}[ADP]}{\mathrm{d}t} = k_{\mathrm{a}}\left[ATP - ADP\exp\left(r\left(1 - c/r_1\right)\right)\right] \tag{9}$$

We assume that the total nucleotide concentration, ADP + ATP, is constant, so no differential equation is needed for ATP. The effect of ATP to block the K(ATP) conductance is antagonized by ADP by competitive inhibition:

$$I_{\mathrm{K(ATP)}} = g_{\mathrm{K(ATP)}}\frac{1 + ADP/K_1}{1 + ADP/K_1 + ATP/K_2}(V - V_{\mathrm{K}}) \tag{10}$$

The net result is that a rise in c results in a slow (minutes) rise in ADP and an increase in $I_{\mathrm{K(ATP)}}$. An increase in glucose can now be represented by an increase in the parameter r in equation 9 in combination with changes in pump rates. We illustrate this in Figure 5 for the situation where glucose is raised from a subthreshold level to a level that permits bursting. Low glucose is simulated by reducing r and SERCA pump rate, k_{SERCA}, which drains the ER and elevates ADP. Starting in that condition, we assume that when glucose is raised, k_{SERCA} increases rapidly,

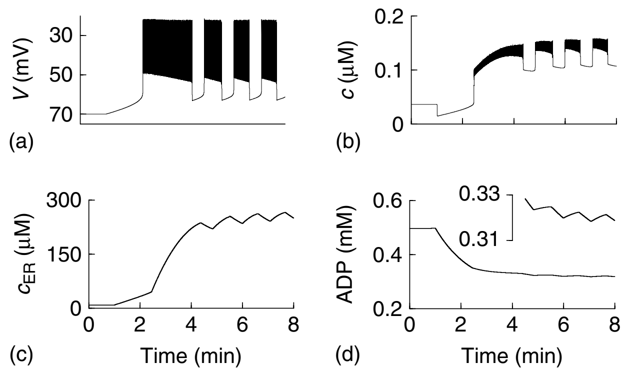

Figure 5 Model with ER and calcium feedback on nucleotide dynamics. Glucose is stepped at $T = 1$ min, initiating a triphasic transient (see text). In the steady state, ADP oscillates as well as cytosolic and ER calcium

producing a transient drop in c (Figure (5)b). Over several minutes, ADP declines, reducing K(ATP) conductance, and V gradually increases. When the voltage threshold for activation of I_{Ca} is reached, V jumps up sharply and spiking begins. The ER, however, is still depleted and acts as a sink for Ca^{2+}. This limits activation of the K(Ca) conductance, resulting in a prolonged period of spiking. After several more minutes, the ER is filled, and bursting can begin. ADP oscillates during the bursting phase (inset, Figure (5)d) and combines with c to drive the bursting. Thus, with inclusion of dynamics for ADP, the model is able to account for the complex triphasic transient of electrical and cytosolic Ca^{2+} activity observed experimentally (Bertram *et al*., 1995b; Goforth *et al*., 2002; Worley *et al*., 1994).

The incorporation of two very slow processes, c_{ER} and ADP, makes the model more robust and endows it with some redundancy. This may help account for the observations that oscillations can persist when the ER is disabled by blocking SERCA (Fridlyand *et al*., 2003) (K(ATP) can compensate for the loss of K(Ca)) or when K(ATP) channels are blocked by sulfonylureas (Rosario *et al*., 1993) (K(Ca) can compensate for the loss of K(ATP)). (See also Bertram and Sherman, 2004.) A third slow process recently proposed by Fridlyand *et al*. (2003), Na^+ accumulation that activates the Na^+ pump, might also be helpful to explain this complex phenomenology.

6. Summary and prospects

We have traced in outline the evolution of the Chay–Keizer family of models over 20 years. The first models explained bursting of membrane potential and modulation of plateau fraction by glucose. They also predicted oscillations of cytosolic Ca^{2+}, which were later seen, but with a different kinetic character. This led to a second wave of models with more accurate Ca^{2+} kinetics, and predictions of oscillations in ER Ca^{2+}. The latter have not yet been demonstrated experimentally, and indeed their existence has been challenged on the basis of ER measurements in

permeabilized cells (Tengholm *et al*., 2001). Measurements of ER Ca^{2+} in intact cells undergoing cytosolic Ca^{2+} oscillations are needed to test this prediction.

The current generation of models can account for the full range of observed oscillation periods, spanning 2 orders of magnitude, from seconds to minutes. They also account for modulation of electrical activity (and, implicitly, insulin secretion) by cholinergic stimuli as well as glucose (Figure 4), and the complex transients seen when glucose is first elevated (Figure 5). The initial prolonged spiking phase may be related to the early large peak of insulin secretion, which is lost in Type II diabetes (Kahn, 2001). However, a serious treatment of secretion will require consideration of the dynamics of vesicle exocytosis and recycling (Rorsman and Renstrom, 2003) in response to both local (submembrane) and bulk cytosolic Ca^{2+} and also to non-Ca^{2+} signals.

Future models will need to address other modulators, such as glucagon-like peptide, which potentiates secretion by elevating cAMP, and epinephrine, which blocks secretion and slows down oscillations. The former pathway is a drug target of great current interest because, unlike K(ATP) channel blockade, it is only effective when glucose is elevated, eliminating the danger of therapy-induced hypoglycemia. Recent data indicate that insulin may have both stimulatory and inhibitory effects on its own secretion (Khan *et al*., 2001). This is an unsettled area that merits further investigation both experimentally and theoretically.

We have included metabolic oscillations based on Ca^{2+}-dependent effects in the mitochondria (Figure 5). However, there is also some evidence for glycolytic oscillations (Tornheim, 1997). One possible role of glycolytic oscillations is in explaining the packaging of the bursts themselves into higher-order patterns, or "bursts of bursts" (Wierschem and Bertram, 2004), and other roles are currently under investigation.

For brevity, we have described here only models for a single cell, representing an electrically synchronized islet. For an overview of models that explicitly treat the nonobvious effects of electrical coupling, see Sherman (1996).

Thanks to judicious pruning of unnecessary detail, the current models are similar in complexity to the original Chay–Keizer model, in spite of their greater explanatory power. The use of simple models has paid dividends in terms of insight and mathematical analysis that goes beyond mere simulation. Of particular note is the establishment of a general classification scheme for burst mechanisms (Bertram *et al*., 1995a). This has not only enhanced our understanding of the β-cell models but also situated them in a general perspective of bursting models for neurons and other secretory cells.

The β-cell has provided an interesting case study of the interaction of physiology and modeling with genomic methods. For example, the K(ATP) channel was identified by physiological experiments, and its possible roles, as either a passive modulator or active participant in oscillations, have been clarified by modeling. In parallel, sequencing has suggested how its structure underlies its function, and genetic scans have uncovered connections to disease (hyperinsulinism and Type II diabetes). Yet, we do not yet know why, according to limited data, in rats glucose appears not to modulate plateau fraction, but rather gross depolarization (Antunes *et al*., 2000), similarly to ACh in mice (Figure 4). The islet α-cells in both species also possess K(ATP) channels, but their response is just the reverse

of β-cells – electrical activity and secretion are inhibited by glucose. How such different behaviors can arise in cell types that differ in rather subtle and quantitative ways poses a challenge for future studies integrating all the techniques at our disposal.

Short Specialist Review

EGFR network

Stanislav Y. Shvartsman
Princeton University, Princeton, NJ, USA

In 1962, a peptide purified from the salivary gland of a mouse was shown to accelerate incisor eruption and eyelid opening in newborn mice. The peptide was named the epidermal growth factor (EGF) (Cohen, 1962). Soon thereafter, EGF and members of the family of peptide growth factors had been identified in countless physiological and pathological contexts. EGF binds to a cell surface receptor (EGFR, epidermal growth factor receptor), inducing its dimerization and phosphorylation of several tyrosines residues within its cytoplasmic tail. The phosphorylated tyrosines provide binding sites for cytoplasmic proteins; this couples the activated receptor to the signal transduction cascades and, eventually, to gene expression and processes such as cell division, differentiation, or migration. Abnormal EGFR signaling due to overactive receptors or overexpressed ligands leads to developmental defects and is also associated with many types of cancers. This much was understood about the EGF system when the 1986 Nobel Prize in Medicine was awarded to Stanley Cohen and Rita Levi-Montalcini for their discovery of EGF and NGF (nerve growth factor).

Today, the EGFR is the subject of some 30 000 research papers. Many individual molecules mediating the EGFR-induced responses have been identified and are drug targets in oncology and other areas of medicine (Yarden and Sliwkowski, 2001). Genomics and proteomics approaches will soon make it possible to follow all genes and protein/protein interactions affected by EGFR/ligand binding on the cell surface. The structural details of EGFR interaction with its ligands are becoming progressively understood at the atomistic level and can be followed in real time with modern imaging tools (Burgess *et al*., 2003). However, neither the contribution of EGFR to tissue morphogenesis in development nor the exact role of deregulated EGFR signaling in disease processes is understood at this time. For example, the mechanistic explanation of the EGF-induced eyelid opening is only beginning to emerge and the attempts to use EGFR expression as prognostic marker in cancer have met with only limited success (Arteaga, 2003).

Quantitative models are necessary in order to deal with the immense complexity associated with the large number of signaling components and multiple feedback loops in the EGFR network (Wiley *et al*., 2003). Synthesis of the existing information into quantitative models is becoming possible due to the highly conserved nature of EGFR signaling and the ability to test the constructed models in well-developed experimental systems. Only a few dozen out of

~30 000 EGFR-related Medline entries are dedicated to modeling and computational analysis. The existing models can be classified into three groups. Models of binding and trafficking describe the levels and cellular location of free and ligand-bound receptors. Explicit models of signal transduction describe the biochemical transformations induced by extracellular ligands at the level of a single cell. Finally, molecular modeling has provided insight into the structural biology of the EGFR system and has guided the design of receptor tyrosine kinase (RTK) inhibitors.

Quantitative models of ligand–receptor binding and trafficking have been indispensable in dissecting the individual steps in the cycle of receptor (and ligand) endocytosis (Wiley, 2003). Using these models to fit data obtained for the kinetics of ligand-induced receptor internalization and degradation, it has been possible to extract the rate constants for different steps within the endocytic cycle. The extracted constants have explained the experimentally observed differences in the biological effects of different EGFR ligands (notably EGF and TGF-α). At the same time, the pharmacological effects of drugs can now be interpreted and predicted in terms of their effects on different steps in receptor-mediated endocytosis. Importantly, the models developed for the EGFR have been successfully used in the quantitative analysis of other ligand–receptor systems.

Several computational models have been used to interpret and plan EGFR signal transduction experiments in cell culture assays. These models accounted for ligand–receptor binding, receptor dimerization, endocytosis, and signal transduction through the PLCγ and MAPK cascades (Schoeberl *et al*., 2002; Kim *et al*., 1999; Haugh *et al*., 2000). The models were used to describe the signals induced by a steplike change in the concentration of exogenous ligand. The predictive capability of these models was demonstrated in two separate cell culture experiments, even though the parameters used for the computational models had been assembled from measurements in multiple cell types and from several in vitro studies.

Almost exclusively, current models of EGFR signaling focus on events at the level of a single cell (or at the molecular level). However, many of the most important in vivo effects of EGFR signaling involve interactions between multiple cells. There are no existing models that describe EGFR signaling at this level, and there is relatively little quantitative understanding that can be translated into directed manipulation of tissue regulation and development. Systematic analysis of EGFR-mediated cell communication requires computational models that simultaneously account for intracellular events *and* intercellular communication by locally produced EGFR ligands. Only with approaches that consider all of these elements simultaneously can predictions be made that are of value on the organismal scale. Given this complexity, integrated models are nontrivial to test experimentally. Appropriate experimental paradigms that can be used to directly test predictions of complex models are critically needed. Cultured epithelial layers and model organisms of developmental genetics, such as the fruit flies, show great promise for achieving this goal (Shvartsman *et al*., 2002; Vermeer *et al*., 2003; Casci and Freeman, 1999).

Even though much of the quantitative studies of EGFR network have assumed that it acts as an independent signaling module, it is highly unlikely that EGFR acts alone in mediating a specific cell or tissue response. Fortunately, an increasing amount of information on how the EGFR system interacts with other pathways,

such as TGFβ and cytokine receptor pathways, promises to help us understand how cells integrate signals from multiple pathways to produce a final response.

Data collection and analysis in systems biology

Trey Ideker
University of California, San Diego, CA, USA

1. Introduction

An exciting trend in molecular biology involves the use of systematic genomic, proteomic, and metabolomic technologies to construct large-scale models of biological systems. These endeavors, collectively known as *systems biology* (Ideker *et al*., 2001a; Kitano, 2002), establish a paradigm by which to systematically interrogate, model, and iteratively refine our knowledge of the cell. While the field of systems science has existed for some time (Ashby, 1958; Bertalanffy, 1973), systems approaches have recently generated a great deal of excitement in biology due to a host of new experimental technologies that are high throughput, quantitative, and large scale. Owing to the time and expense associated with large-scale measurements as well as the enormous amounts of data produced, principled strategies will be indispensable for using these data to construct biological models.

2. Large-scale experimental methods

The first technology to revolutionize modern biology was automated DNA sequencing (Hood *et al*., 1987), which was instrumental in defining the list of 30 000 genes in the human genome (Lander *et al*., 2001; Venter *et al*., 2001). More recently, DNA microarrays have enabled simultaneous measurement of all gene states to reveal which genes are expressed (i.e., turned on vs. off) in a particular cell type or biological condition (Slonim, 2002). Other molecular states, such as changes in protein levels (Gygi *et al*., 1999), phosphorylation states (Zhou *et al*., 2001), and metabolite concentrations (Griffin *et al*., 2001), can be quantified with mass spectrometry, nuclear magnetic resonance, and other advanced technologies. A final cellular state measurement that is gaining in importance is the genomic phenotyping experiment (Begley *et al*., 2002), also called *parallel phenotypic analysis* (Deutschbauer *et al*., 2002). In this type of experiment, a library of

gene knockouts is screened to identify which genes are essential for a particular phenotype. In single-celled organisms, the phenotype associated with each gene is typically the growth rate, but it can really be any measure of the phenotypic consequences of perturbing a gene.

Of the approaches for characterizing cellular states, measurements made by DNA microarrays are currently the most comprehensive (every mRNA species is detected); high throughput (a single technician can assay multiple conditions per week); well characterized (experimental error is appreciable, but understood); and cost-effective (whole-genome microarrays are purchased commercially for US $50 to $1000, depending on the organism). However, continued advances in protein labeling and separation technology are making measurement of protein abundance and phosphorylation state almost as feasible, with the primary barrier being the expense and expertise required to set up and manage a mass spectrometry facility. Measurement of metabolite concentrations, an endeavor otherwise known as *metabonomics* (Nicholson *et al*., 2002), is currently limited not by detection (thousands of peaks, each representing a different molecular species, are found in a typical NMR spectrum) but by identification (matching each peak with a chemical structure is difficult). Clearly, measuring changes in cellular state at the protein and metabolic levels will be crucial if we are to gain insight into not only regulatory pathways but also those pertaining to the cell's signaling and metabolic circuitry.

Equally as exciting, another set of recent technological advances have enabled us to characterize DNA and protein interaction *networks.* Several methods are available for measuring protein–protein interactions at large scale – two of the most popular being the yeast two-hybrid system (Uetz *et al*., 2000b; Fields and Song, 1989) and protein co-immunoprecipitation (coIP) followed by mass spectrometry (Gavin *et al*., 2002; Ho *et al*., 2002a). Protein–DNA interactions, which commonly occur between transcription factors and their DNA binding sites, constitute another interaction type that can now be measured at high throughput using the technique of Chromatin ImmunoPrecipitation followed by promoter microarray chip analysis (ChIP-chip) (Iyer *et al*., 2001; Ren *et al*., 2000). Large protein–protein or protein–DNA interaction data sets are now available for a variety of species including *Saccharomyces cerevisiae* (Uetz *et al*., 2000a; Lee *et al*., 2002; Ito *et al*., 2001; Ho *et al*., 2002b; Gavin *et al*., 2002), *Helicobacter pylori* (Rain *et al*., 2001), *Drosophila melanogaster* (Giot *et al*., 2003), and *Caenorhabditis elegans* (Walhout *et al*., 2000; Li *et al*., 2004). Additional types of molecular interactions, such as those between proteins and small molecules (carbohydrates, lipids, drugs, hormones, and other metabolites), are difficult to measure at large scale, although protein array technology (MacBeath and Schreiber, 2000; Zhu *et al*., 2001; Haab *et al*., 2001) might enable high-throughput measurement of protein–small molecule interactions in the near future. A current drawback of high-throughput interaction measurements is a potentially high error rate (Deane *et al*., 2002). An emerging approach for addressing this problem is to construct models that integrate several complementary data sets together (e.g., two-hybrid interactions with coIP data or gene expression profiles) to reinforce the common signal (Bar-Joseph *et al*., 2003; Hanisch *et al*., 2002; Ideker *et al*., 2002; Jansen *et al*., 2002; Yeger-Lotem and Margalit, 2003; Ge *et al*., 2001).

3. Modeling and systems analysis

The enormous amount of data arising from high-throughput biology provides a more complete picture of cellular function than ever before. However, new data sets are being generated at a rate that far outpaces our ability to analyze and interpret the results – a disparity that has thus far limited the impact of these data on basic biomedical research. Eliminating this disparity therefore presents a number of grand challenges to computational researchers: how to best associate high-level information about proteins and protein interactions with functional roles; how to enrich the true biological signal in noisy data; and, most importantly, how to organize global measurements at different levels into full-fledged models of cellular signaling and regulatory machinery.

Systems biology attempts to address these goals by integrating the various levels of global measurements together and with a mathematical model of a biological system or pathway of interest. Although these model-driven approaches may differ in the particulars of implementation, all follow a fundamental framework involving the following four distinct steps (Figure 1):

1. *Define the System Components.* Discover all of the genes in the genome as well as the particular molecules and molecular interactions that constitute the pathway of interest. If possible, define an initial model of how these molecular components and interactions relate to govern pathway function.
2. *Perturb the System.* Perturb each pathway component through a series of genetic or environmental manipulations. Detect and quantify the corresponding global cellular response to each perturbation, using genomic, proteomic, and/or metabolomic technologies.

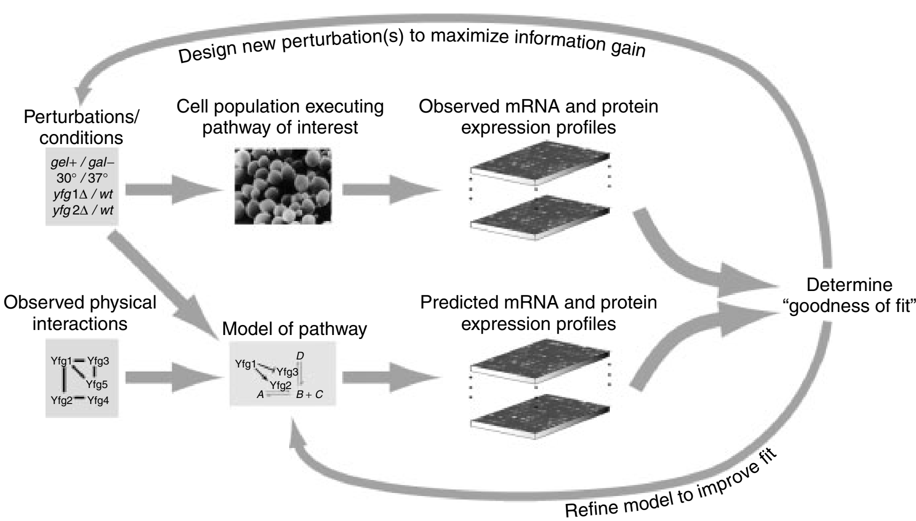

Figure 1 A systems approach to biology. (Reprinted, with permission, from the Annual Review of Genomics and Human Genetics, Volume 2 © 2001 by Annual Reviews **www.annualreviews.org**)

3. *Model Reconciliation.* Integrate the observed responses with the current pathway model and with the global networks of protein–protein interactions, protein–DNA interactions, and biochemical reactions.
4. *Model Verification/Expansion.* Formulate new hypotheses to explain observations that are not predicted by the model. Design additional perturbation experiments to test these and iteratively repeat steps (2), (3), and (4).

Steps (1) and (2) are focused on biological *discovery* through construction of a library of potential components, interactions, and system responses. Steps (3) and (4) are driven by a set of hypotheses encoded by the computational models. Systems approaches following this general framework have been used most actively to interrogate pathways in model organisms, including yeast (Forster *et al*., 2003; King *et al*., 2004; Ideker *et al*., 2001b; Bar-Joseph *et al*., 2003), *Escherichia coli* (Gardner *et al*., 2003), *Halobacterium* (Baliga *et al*., 2002), and sea urchin (Davidson *et al*., 2002). These works provide a roadmap of how to model cellular processes through large-scale measurement and integration of biological data.

Central to this systems approach are computer-aided models for understanding and interrogating complex cellular processes. These models promise to revolutionize biology and medicine by providing a comprehensive blueprint of normal and diseased cell functions and by allowing researchers to simulate the effects of drugs on cells long before they are tested in humans. Several strategies have been developed for integrating gene expression profiles with other large-scale data to formulate models of regulatory networks, including Bayesian learning, neural nets, process algebra, and systems of differential equations [for a review, see van Someren (van Someren *et al*., 2002)]. Computer-aided approaches for experimental design are equally as important – that is, designing perturbations to most effectively and efficiently verify and expand the models in step (4) above (Tong and Koller, 2001; King *et al*., 2004; Ideker *et al*., 2000).

With the recent appearance of large networks of protein–protein and protein–DNA interactions as a new type of measurement, systems researchers are trying to identify the specific network structures and network "design principles" that have been most favored by evolution. These efforts have shown that biological networks encode modular functional units (Rives and Galitski, 2003; Ravasz *et al*., 2002) that have likely evolved to be robust to perturbation (Jeong *et al*., 2001). Moreover, these modules often contain recognizable configurations such as the feedback and feed-forward loops that are also prevalent in electronic circuitry and other types of man-made systems (Milo *et al*., 2002). Several other groups have proposed methods for constructing regulatory models of the cell, using molecular interaction networks as the central framework (Bar-Joseph *et al*., 2003; Kelley *et al*., 2003; Hanisch *et al*., 2002; Ideker *et al*., 2002; Jansen *et al*., 2002; Yeger-Lotem and Margalit, 2003; Ge *et al*., 2001). The key idea is that, by identifying which parts of the molecular interaction network correlate most strongly with other biological evidences such as gene expression profiles or genomic phenotypes, it will be possible to organize the network into circuit modules representing the repertoire of distinct functional processes in the cell. Several approaches are also available for identification of metabolic pathways or protein complexes that have

been conserved over evolution (Kelley *et al*., 2003; Forst and Schulten, 2001; Dandekar *et al*., 1999). Evolutionarily conserved pathways allow interpretation of the network of a poorly understood organism based on its similarity to that of a well-known species. These tools also have application to infectious disease, for example, by targeting drugs to pathways that are present in a pathogenic organism but absent from its human host.

4. Current and future challenges

Systems biology now faces several major challenges. First, given a first-generation toolbox of modeling and systems approaches, an immediate next step is to leverage these tools to elucidate disease pathways. However, although systems approaches have been successfully applied to species such as *S. cerevisiae* (Gavin *et al*., 2002; Ho *et al*., 2002a; Habeler *et al*., 2002; Gygi *et al*., 1999; Haab *et al*., 2001; Kumar *et al*., 2002; Lee *et al*., 2002; Tong *et al*., 2001; Uetz *et al*., 2000b), similar studies in medically relevant organisms such as human, mouse, and rat have remained largely out of reach. This disparity is due to the increased complexity of mammalian systems; technical and ethical problems in subjecting them to perturbation; and a relative lack of experimental data on protein–protein, protein–DNA, or other molecular interactions for human. Encouragingly, ongoing data production efforts in human cell lines (e.g., the Alliance for Cell Signaling; **http://www.afcs.org**) and emerging technologies such as RNAi gene knockdowns (Dykxhoorn *et al*., 2003) promise to address many of these difficulties in the near future. In the meantime, yeast remains an attractive alternative for studying basic biological pathways that influence pathogenesis and genetic disorders.

A second challenge is that almost all previous systems biology studies have been strongly reliant on a preexisting model of the pathway of interest. For instance, in our case study of the galactose-utilization pathway (Ideker *et al*., 2001b), the initial components and interactions of the model were drawn directly from review articles and the primary literature. An initial literature-based model was also indispensable for the now classic explorations of bacterial chemotaxis (Barkai and Leibler, 1997) and infection by phage lambda (Arkin *et al*., 1998; McAdams and Shapiro, 1995). These studies significantly expanded our biological knowledge, but if systems approaches continue to be successful, they will quickly exhaust the few well-studied biological systems that are available. Therefore, systems biology will only become a sustainable paradigm if it can generate new models in the absence of extensive prior knowledge.

If these challenges can be met, it is likely that systems and modeling approaches will have substantial payoffs in basic medicine as well as the pharmaceutical industry. In this regard, it is revealing that outside of biotechnology, many sectors of manufacturing already depend heavily on computer simulation and modeling for product development. Using computer-aided design (CAD) tools, digital circuit manufacturers explore the wiring of transistors and other components on the silicon wafer, just as automotive engineers estimate how many miles per gallon is to be expected from the next-generation sedan long before it is built on the assembly line. Biology will undoubtedly also benefit from these “classical” engineering

approaches. Given that more than six out of every seven drugs that undergo human testing ultimately fail because of unanticipated side effects, systems modeling may act as a much-needed filter between high-throughput screening for drug candidates and the time-consuming and costly follow up of human trials.

5. Perspective

The field of systems biology still faces many challenges but also holds much promise. By increasing our basic repertoire of experimental strategies and modeling approaches, systems biology provides the starting point for advances in many facets of biotechnology, not least of which is an enhanced ability to appropriately target therapeutics in diseased cells. Thus, we can move one step closer to the day when systems modeling techniques will have widespread influence on basic biological research and replace high-throughput screening as a de facto standard in drug development.

Introductory Review

Contig mapping and analysis

Asim Siddiqui and Steven Jones
British Columbia Cancer Agency, Vancouver, BC, Canada

The creation of ordered sets of overlapping clones or "contigs" has historically been the goal of chromosome walks in gene hunting and more recently in providing tiling paths of clones for whole genome sequencing. Various methods have been used to establish clone overlaps, including simple cross hybridization. In radiation hybrid mapping, the overlaps between the propagated large genomic fragments are detected through shared Sequence Tags Sites (STSs) detected through PCR amplification (Cox *et al*., 1990). Currently, the most common way to establish clone overlaps is through shared restriction fragments.

Restriction enzyme fingerprint mapping has undergone a number of iterations in its development. However, the basic concept remains the same. A set of clone fragments is derived by cutting the clone with a restriction endonuclease that matches a very short (4 or 6 bp) nucleotide sequence. The fragments from each clone are then sized using an electrophoresis technique. Clones that overlap will share a number of similarly sized fragments. The earliest methods used radioactive labeling and acrylamide gels (Nathans, 1979). Using an essentially similar method, Coulson *et al*. (1986) generated a preliminary version of the *Caernorhabditis elegans* physical map by using Cosmid clones libraries. The contiguation of this map was later substantially improved through the addition of YAC clones to the contigs (Coulson *et al*., 1988). The larger insert size of YAC clones allowed them to bridge gaps in the coverage of the Cosmid clone map. The relatively small size of cosmids, approximately 30–40 kb, remained a limitation in the ability of such fingerprinting techniques to map large plant and mammalian genomes until the development of Bacterial Artificial Chromsomes (BACs) with a much larger insert size of between 180 and 200 kb (*see* Article 3, **Hierarchical, ordered mapped large insert clone shotgun sequencing**, Volume 3). Other improvements, such as the use of agarose instead of acrylamide gels also made the approach amenable to high-throughput data generation and has been used to create physical maps for a number of mammalian genomes including human (McPherson *et al*., 2001), mouse (Gregory *et al*., 2002), and rat (Krzywinski *et al*., 2004). In this chapter, we will discuss the methods and approaches used in contiguating clones on the basis of restriction fragment fingerprint information.

A genomic library consists of a set of overlapping clones representing coverage of the whole genome. By identifying common overlap regions between clones, clones that have adjacent positions in the complete genome may be found and

joined together in a common contig. The level of redundancy in the genome coverage of a library is often quoted as "X coverage". For example, in a 4X genomic library, any section of DNA is represented on average in four different clones – see Figure 1. The average coverage can be calculated by simply multiplying the average insert size of the library by the number of clones in the library and dividing by an estimate of the genome size. Since short clone overlaps are difficult to reliably detect, the joining of the clones is more likely to be reliable with a high redundancy of clone coverage, which will also reduce the number of gaps in clone coverage.

To generate a restriction enzyme fingerprint map, the clone insert is cut by a restriction endonuclease that recognizes a short, specific nucleotide sequence. This breaks the clone into a series of fragments, the largest of which are around 30 kb in length. By separating the clone fragments using an electrophoresis gel, it is possible to size each of the fragments. This record of the sizes of fragments represents the fingerprint of the clone. Owing to limitations of gel electrophoresis, fragments that are less than 600 bases in length are not recovered. By fingerprinting all of the clones using the same restriction enzyme, clones with similar fingerprints, that is, those containing similarly sized fragments, can be identified and they will likely overlap. The probability that two clones overlap increases as a function of the number of bands their fingerprints have in common. The Sulston score (Sulston *et al*., 1988) defines that probability that *im* or more bands matching between two

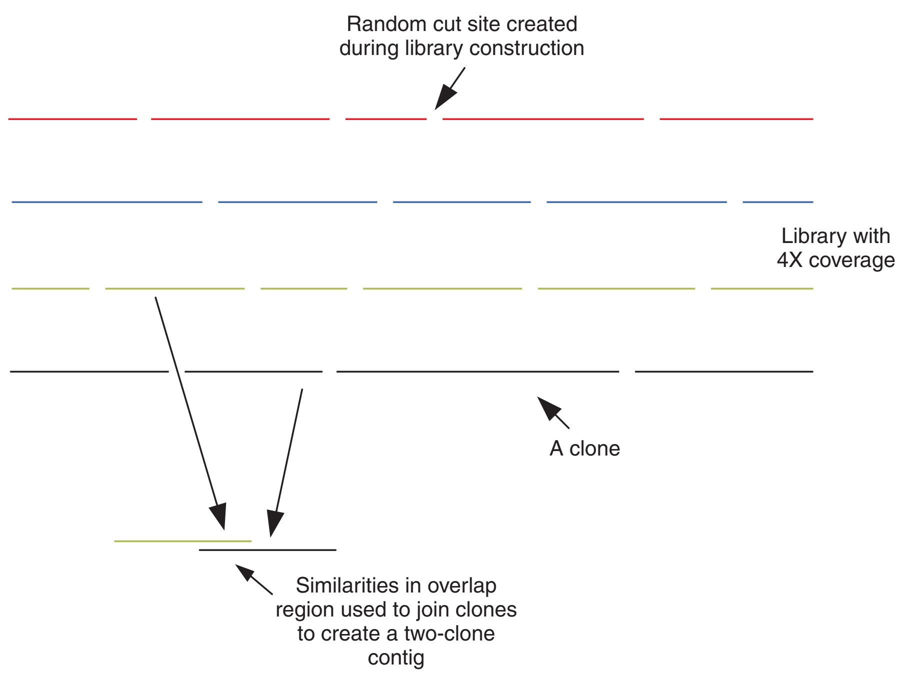

Figure 1 A representation of clones in a genomic library with 4X coverage. Each colored line represents a different copy of the original genomic DNA. Each fragment in each line represents an individual clone. Overlaps between clones can be used to identify the two clones as neighbors

fingerprints do so by chance in the following way:

$$S = \sum_{n=im}^{n=nbandl} \left[\frac{nbandl\,!}{(nbandl\ - n)!n!} * (1 - p)^n\, p^{(nbandl - n)} \right] \tag{1}$$

where *nbandl* is the number of bands in the clone with the fewer bands, *nbandh* is the number of bands in the clone with more bands and

$$p = \left(1 - \frac{2 * tolerance}{gellength}\right)^{nbandh} \tag{2}$$

The *tolerance* is a measure of the experimental error in determining the position of the band (and hence the size of the fragment). The equation assumes that all bands are equally likely. Hence, the probability of a single band in the gel with fewer bands matching one band in the gel with more bands is given by

$$\frac{2 * tolerance}{gellength} \tag{3}$$

which leads to equation (2), which is the probability that a single band in the fingerprint with fewer bands matches no bands in the other fingerprint. Since the number of matches between the fingerprints will follow a binomial distribution, the extension of equation (2) for all bands leads to the Sulston score, equation (1).

The Sulston score forms the basis for the FPC (FingerPrinted Contigs) software (Soderlund *et al*., 1997). Figure 2 shows a screenshot from the FPC software. This software is used to manage the process of creation of clone contigs. FPC performs an automated fast assembly of the clones producing a set of ordered and "buried" clones. A buried clone is one that contains no identifiable unique fragments and whose entire sequence may be wholly represented by another clone. In this case, the clone is "buried" in the clone that contains it. Clones that contain at least one unique fragment cannot be buried and are referred to as *canonical clones* (Figure 3).

The FPC algorithm works by first calculating the Sulston score for each pair of clones, burying clones that are an exact or a close match to another clone, and then building a consensus band map (CB map). The CB map is initially built using a hybrid greedy/stochastic algorithm to identify adjacent clones, which is then greedily extended.

Unfortunately, both the experimental methods and computational methods for identifying and sizing clone fragments are subject to experimental error. Therefore, it is not possible to create a perfectly ordered CB map and the CB map created by FPC must be refined by manual methods. A common problem is when a band is missed (undercalled) or a band is identified when none is present (overcalled). This problem is particularly evident when bands are very close together such that they cannot be resolved as separate bands on the gel, but may also be due to faint bands. A human map analyst can use FPC to review gel images and reorder clones by correcting for overcalled or undercalled bands to create the most likely clone order. This is a manually intensive task and is the bottleneck in the production of high

Figure 2 A screenshot from the FPC software. The clone names (e.g., H005D09) run across the page near the top of the figure and the fragment mobilities (related to fragment size) are on the left-hand side of the figure. The scanned gel images for each clone run down the page. On either side of the scanned image are horizontal bars that show where the band-calling software has identified a band. The figure shows examples of faint bands that have not been called by the software (undercall) and thick bands where the number of fragments composing the band is unclear and may result in too many bands being identified (overcall)

quality maps. Correcting for these artifacts in an automated manner is an active area of research and requires either improving the data quality (Fuhrmann *et al*., 2003) or improving the ordering and burying algorithm (Flibotte *et al*., 2004). Bandleader analyses the pixel values of a scanned gel image to identify bands. By assuming a Gaussian signal for a band, it is able to improve the resolution of image using standard signal processing techniques. CORAL uses a machine-learning algorithm to improve the burying and ordering of an FPC map.

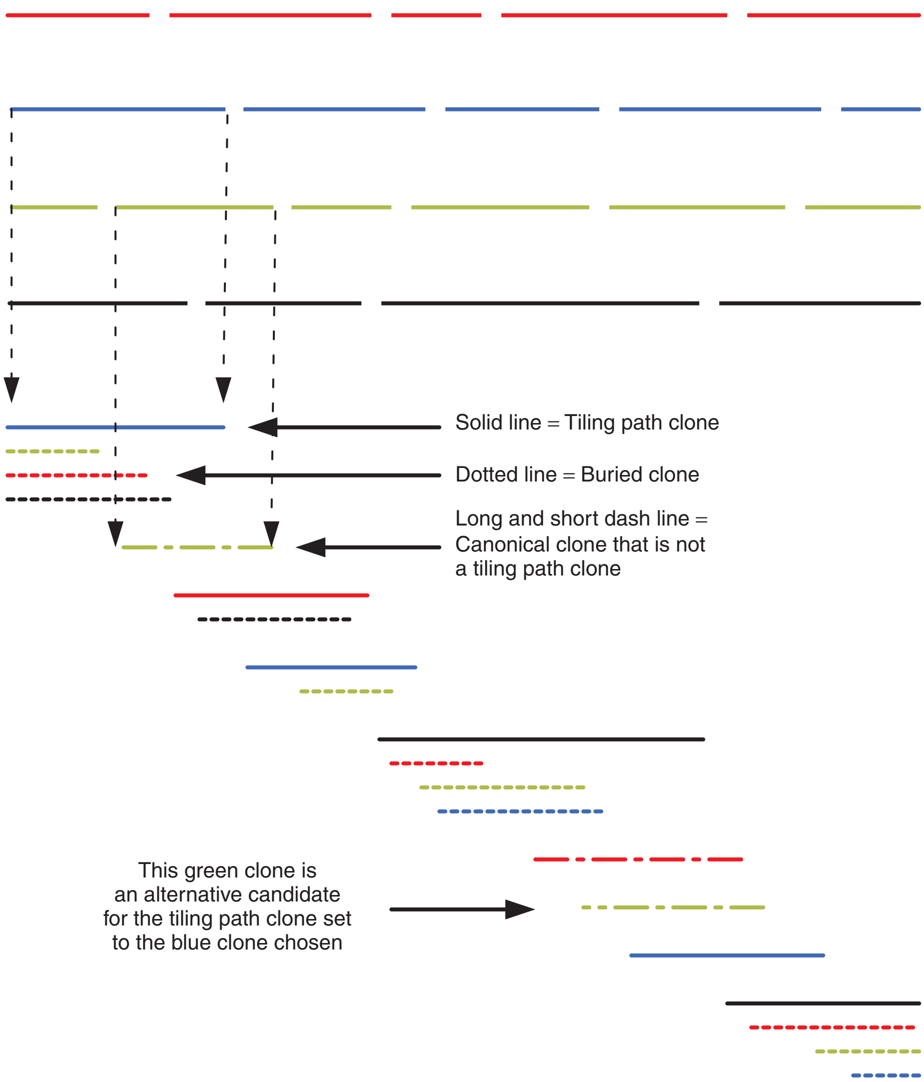

Figure 3 The different clones in Figure 1 have now been joined together to form a map contig. Dotted clones have their sequence fully represented by another clone are termed buried clones. Clones that cannot be buried (solid line and alternating dash/dot) are called canonical clones. From the canonical clones, a minimal set of tiling path clones have been selected (solid line) that represent all of the genomic DNA covered by this map contig with little or no redundancy. Note there are alternative clones that could have been selected when choosing clones for the tiling path

Another common problem is the creation of chimeric clusters that contain clones from a different part of the genome. These clones have been placed together because they have high Sulston scores by chance. FPC provides a framework and the necessary software tools for the map analyst to manipulate the clone order, change buried clones, and tease apart chimeric clusters.

Further difficulties are caused by genomes that contain a large number of repeat regions, such as plant genomes. The repeat regions tend to be compressed in fingerprint-based physical maps since if the genome contains the enzyme site, a repeat region will cause the overrepresentation of a band in the fingerprint, while if there is an absence of an enzyme site, this will lead to a large fragment that is not cut by the enzyme (Chen *et al*., 2002). There have been some attempts to improve the ordering and burying provided by the raw Sulston score. Soderlund and coworkers incorporated marker data into the original FPC software (Soderlund *et al*., 2000). The markers (for example, based on STS data) were used in conjunction with the fingerprint data to enhance the score. If two clones share markers, the cutoff of the Sulston score for the clones to be related is lowered by an order of magnitude for each marker they share. A further improvement to FPC has been the creation of a parallel version that distributes the calculation of the Sulston score for all pairs of clones across the nodes of a cluster (Ness *et al*., 2002). This reduces the time to create an FPC map making it feasible to optimize build parameters by running multiple FPC builds.

Software available for viewing an FPC map includes WebFPC (available from **http://www.genome.arizona.edu/software/fpc**) and Internet Contig Explorer (Fjell *et al*., 2003). Further tools allow virtual fingerprints to be created for sequenced clones for addition to the map and the extraction of a minimal tiling set from the map (Engler *et al*., 2003).

As described above, the final set of clones will consist of a number of buried clones and an ordered number of overlapping, canonical clones. Depending on the depth of sampling of the genomic library, several clones may represent any one region of the genome. By identifying a minimum tiling path for the clones (see Figure 3), a set of canonical clones that cover the entire genome with minimal overlap may be extracted. The minimum tiling path may be used as a starting point for sequencing the genome, providing a set of clones that have the same coverage of the genome, but with lower degree of redundancy than the original library, thereby reducing the sequencing cost. Clone tiling paths are also useful in the generation of comparative genomic hybridization (CGH) arrays (*see* Article 23, **Comparative genomic hybridization**, Volume 1) and for fluorescent in-situ hybridization (FISH) experiments (*see* Article 22, **FISH**, Volume 1).

More data can be provided by end sequencing of the clones. In this process, a sequence read is generated from each end of the clone. These reads may be used to help align the physical map with an assembled genome sequence. By aligning the end reads against the sequence, for example by using BLAST sequence alignment program, the clone's position in the genome sequence may be defined (Engler *et al*., 2003). By tying the map assembly to the sequence assembly, it is possible to uncover misassemblies in both the sequence and the map and to identify clone resources that can be used to fill sequence gaps.

This verification can be performed at several levels. Large-scale rearrangements will result in the clone order as determined by the fingerprints to be different from that specified by sequence assembly. The insert size of the clone (i.e., the length of DNA sequence that was inserted into the BAC or YAC) can be determined by summing the sizes of fragments in the fingerprint. This insert size will be an underestimate since small fragments (less than 600 bp) cannot be measured.

The insert size can be calculated for each clone individually or alternatively an average insert size can be calculated for the library (insert sizes for high-quality genomic libraries follow a pseudonormal distribution). Since reads from each end of the clone were taken, the sequence assembly can be used to calculate the insert size and this may be compared to the known insert size or average for discrepancies. The Arachne software is capable of incorporating this information (Batzoglou *et al*., 2002).

Resolution at a higher level may be performed by digesting with the assembled sequence in silico to create virtual fingerprints (i.e., finding cut sites in the assemble sequence that match the recognition site of the enzyme used to create the real fingerprints). The in silico fingerprints from the sequence assembly may be compared to the real fingerprints to identify discrepancies. The resolution of this type of analysis may be extended even further by creating additional fingerprints of the clones cut with different enzymes. See Article 8, **Genome maps and their use in sequence assembly**, Volume 7 for more details on how map data may be used to improve sequence assemblies.

There are a number of efforts ongoing to apply fluorescent labeling in conjunction with capillary electrophoresis using a DNA analyzer to automatically size fragments. The latest methods extend this technique by performing multiple digests using different enzymes and labeling the ends of the fragments to identify fragments cut by the same enzyme (Luo *et al*., 2003) or to sequencing 1–4 bases at the 5′ end of the fragment (Ding *et al*., 2001). Although a DNA analyzer presents an upper limit on the size of fragments that can be measured (about 600 bp), the measurements are much more accurate than those obtained by gel electrophoresis. Hence, the value of the tolerance used in equation (2) is smaller, resulting in a stricter Sulston score probability. This factor and the additional information that these methods provide about each fragment greatly improve the ability to identify related clones. These methods represent the next generation in fingerprinting technology and will allow for substantial improvements in automated methods of contig mapping and analysis.

With the improvement in whole genome shotgun assembly techniques, the generation of a physical map is no longer a necessary precursor to genome sequencing. However, the physical map remains a valuable resource for aiding the assembly of a genome. The correct assembly of a genome sequence from sequence data alone remains a difficult task and the physical map can act as a framework for the assembly. Furthermore, physical maps can be used to generate a set of clones that cover the entire genome with less redundancy than the original genomic library (known as a set of tiling path clones). Since the generation of a clone fingerprint remains relatively cheap, reducing the redundancy of the clones that are to be sequenced can reduce the cost of the sequencing operation.

Specialist Review

Algorithmic challenges in mammalian whole-genome assembly

Serafim Batzoglou
Stanford University, Stanford, CA, USA

1. Introduction

The basic methodology used today for sequencing a large genome is double-barreled shotgun sequencing. Shotgun sequencing, introduced by Sanger and colleagues early on (Sanger *et al*., 1977), involves obtaining a redundant representation of a genomic segment with sequenced reads and then assembling the reads into contigs on the basis of sequence overlap. *Double-barreled* shotgun sequencing enhances this method by introducing the notion of paired-end reads that are obtained by sequencing both ends of a fragment of known size, and thus provides useful long-range linking information (Edwards *et al*., 1990).

It is relatively straightforward to cover an arbitrarily long genome with sequenced reads, so that few gaps remain (e.g., by the Lander–Waterman model (1988), a 10-fold redundancy coverage of the genome with 500-long reads yields less than 1 gap in every 10^6 bp). Sequencing a genome is simple then, if defined as obtaining a representation of the majority of nucleotides in a genome. What makes sequencing challenging is the subsequent computational problem of correctly assembling the reads into the original sequence.

2. Repeats, sequencing errors, and their relationship

Assembly would be easy were it not for repeats. If genomes had the properties of random strings on four letters {A, C, G, T}, then it would be unlikely for two reads to share a significant overlap unless they represented overlapping segments in the genome – a *true overlap*. Unfortunately, nearly half a mammalian genome's length consists of repeats, and true overlaps can be confused with *repeat-induced overlaps*. The main challenge of assembly is to distinguish between true overlaps, where reads should be merged, and repeat-induced overlaps, where merging should be (usually) avoided to prevent *misassemblies* – assembled sequence that does not occur in the genome. Repeats come in many varieties. The number of copies ranges

from 2, such as in gene duplications, to about 10^6 in the case of ALU repeats in the human genome. Sequence similarity between copies can be almost 100%, such as in recent duplications, or very low, such as in ancient transposon lineages that have become inactive. Our ability to distinguish between true and repeat-induced overlaps is intimately tied to the sequencing error rate. In essence, if more than a proportion r of sequencing errors is unlikely, then any overlap with more than $2r$ mismatches and gaps is likely to be repeat-induced. Therefore, increasing read accuracy reduces the repeat content of a genome for the purposes of assembly.

3. Two main ways to deal with repeats: clustering the reads and pairing the reads

There are broadly two methods for assembling long genomic regions in the presence of repeats. The first method is *clone-based sequencing*, whereby the reads are being clustered by performing shotgun sequencing on medium-sized segments such as Bacterial Artificial Chromosome (BAC) clones of length ∼200 kb. With this method, the effective repeat content is drastically cut because most segments that are repeated across the genome are unique within such short regions. Moreover, the number of reads to be assembled is reduced by a factor of 10^4, and therefore the computational assembly problem becomes much simpler. The second method is *double-barreled whole-genome shotgun (WGS) sequencing*, whereby paired reads are obtained from both ends of inserts of various sizes (Edwards *et al*., 1990). Paired reads can resolve repeats by jumping across them: when taken from plasmid inserts longer than 5000 bp, they can resolve LINE repeats of that length; paired reads from longer inserts such as cosmids and BACs can resolve duplications, help build longer scaffolds, and verify the large-scale accuracy of an assembly.

4. Clone-based sequencing

Clone-based sequencing was used to sequence several genomes including those of the yeast *Saccharomyces cerevisiae* (Oliver *et al*., 1992; Dujon, 1996), *Caenorhabditis elegans* (The C. elegans Sequencing Consortium, 1998), *Arabidopsis thaliana* (The Arabidopsis Genome Initiative 2000), and humans (International Human Genome Sequencing Consortium, 2001). Most applications of clone-based sequencing were performed under the “map first, sequence second”, or *physical mapping* approach. Physical mapping involves constructing a complete physical map of a large set of clones covering the genome with redundancy, and then selecting a minimal tiling subset of those clones to be fully sequenced. After sequencing and assembly, errors in the original map, gaps, and misassemblies can be spotted, and if necessary, corrected with additional targeted sequencing. This approach was successfully used to generate physical maps for sequencing the *S. cerevisiae* and *C. elegans* genomes (Coulson *et al*., 1986; Olson *et al*., 1986). The human genome was also sequenced by the public consortium using this approach, although the first draft large-scale assembly was still a challenging

computational task: ordering and orienting the assembled contigs into a global genome assembly required integration of various sources of information such as sequence overlap, mRNA, and EST fragments, and end-sequencing of BACs. All these pieces of evidence were put together by a specialized system called *GigAssembler* (Kent and Haussler, 2001). Physical mapping is by no means the only possible way to perform clone-based sequencing. Other methods are possible but less explored, such as the walking approach (Venter *et al*., 1996; Batzoglou *et al*., 1999; Roach *et al*., 1999; Roach *et al*., 2000), or light shotgun sequencing of completely unmapped random clones, whereby a collection of clones covering the genome with redundancy C_1 are sequenced to redundancy C_2 for a total sequencing depth C_1C_2. As clustering directly addresses the repeat challenge by effectively eliminating most repeats, assembly under any of the above schemes is, in principle, easier than under double-barreled sequencing.

5. Whole-genome shotgun sequencing

Shotgun sequencing was initially applied by Sanger to the genome of bacteriophage λ (Sanger *et al*., 1980, 1982). Over the years, shotgun sequencing has been applied to genomic segments of increasing length. In the 1980s, it was applied to plasmids, chloroplasts (Ohyama *et al*., 1986), viruses (Goebel *et al*., 1990), and cosmid clones of length roughly 40 kb, which were considered to be the limit of this approach. In the 1990s, mitochondria (Oda *et al*., 1992), BACs of length 200 kb carrying genomic DNA from human or other organisms, as well as the entire 1800 kb genome of the bacterium *H. influenzae* (Fleischmann *et al*., 1995) were sequenced. Compared to clone-based shotgun sequencing, WGS poses a much harder computational challenge, especially in large, repeat-rich genomes. When a WGS strategy was proposed for sequencing a mammalian genome such as human (Weber and Myers, 1997), scientists debated whether such as strategy would succeed (Green, 1997). Today, we know that this is possible, as demonstrated by WGS assemblies of several complex genomes such as *Drosophila melanogaster* (Myers *et al*., 2000), human (Venter *et al*., 2001), and mouse (Mouse Genome Sequencing Consortium, 2002; Mural *et al*., 2002). These successes have brought computer science to the forefront of genomics: WGS assembly became possible through advances in algorithms and software systems rather than in either computer processor speed or sequencing accuracy.

6. Overview of WGS assembly

The prevailing methodology for WGS assembly is the three-stage *overlap-layout-consensus* strategy (Peltola *et al*., 1984; Kececioglu, 1991; Huang, 1992; Kececioglu and Myers, 1995). During the *overlap* phase, all read-to-read sequence overlaps are detected. During *layout*, subsets of the overlaps are selected in order to merge reads into longer scaffolds of ordered and oriented reads. Those scaffolds are converted into sequence through a multiple alignment during the *consensus* phase. One of the most successful systems employing this three-phase strategy is

PHRAP (Green, 1994), which has been the standard for BAC-size assembly, but is unable to handle whole mammalian-size genomes. Current WGS assemblers include the Celera assembler (Myers *et al*., 2000), Euler (Pevzner *et al*., 2001), Arachne (Batzoglou *et al*., 2002; Jaffe *et al*., 2003), Phusion (Mullikin *et al*., 2003), Atlas (Havlak *et al*., 2004), and others. Most of these systems, at least implicitly, use the overlap-layout-consensus strategy.

In the following paragraphs, we will briefly describe each of the assembly phases, focusing on the challenges they pose and on the algorithms that current WGS assemblers employ to address these challenges. We will be using the following terminology: a *contig* is a multiple alignment of reads, which can be converted into contiguous genomic sequence during the consensus phase. A *supercontig* is a structure of ordered and oriented contigs, usually derived by linking contigs according to paired reads. Some papers refer to *ultracontigs* as higher structures of supercontigs that are derived by various sources of linking information, such as paired reads from large inserts, mapping of BAC clones, or even cross-species comparison. The general term for assembled structures is the *scaffold*, a term usually interchangeable with supercontig. As the layout phase is the most complex, a useful conceptual (and implementation) division of this phase is in two subphases: (1) *contig layout*, during which most assembly systems strive to identify repeat boundaries and connect the reads into *contigs* that are as long as possible without crossing those boundaries, as that would induce misassemblies and (2) supercontig assembly, perhaps the hardest phase of all, where contigs are chained into longer structures by use of paired reads crossing contig boundaries, and subsequently, gaps are filled and misassemblies are identified and remedied.

7. The overlap phase

In the *overlap* phase, read-to-read sequence overlaps are detected. Note that since read orientation is not known, all overlaps between reads in forward or reverse complement direction are detected. The nature of the data requires several preprocessing tasks to take place prior to overlap detection, such as trimming of reads to remove bases with quality scores that are too low and filtering of contamination from sequencing/cloning vector or mitochondrial sequences. Next, in the case of large-scale WGS, a significant algorithmic challenge is to find the overlaps efficiently. The strategies that have been employed rely on detecting exact word matches between the reads. Celera, Phusion, and Arachne, all perform a global step of indexing all exact fixed-length word occurrences in the reads and then aligning all pairs of reads that share a word. Prior to alignment, filtering of very frequent words is necessary to avoid a huge number of pairwise read matches. Phusion and Arachne mask all highly repetitive k-mers, while Celera masks repeats, a step that is inherently more conservative and will discard additional spurious matches, but is also more complicated. Alignment is done with fast procedures that rely on the fact that only almost exact sequence identity between two reads can induce an overlap. Phusion and Arachne's original indexing strategies were more time-efficient, but required more memory, than Celera's strategy. Arachne performs this step in several passes, trading off speed for memory.

Upon detecting potential read overlaps, most assemblers filter them so as to remove the ones that are very likely to be repeat-induced. Arachne and Euler in particular, use a sequencing error-correction strategy that greatly simplifies subsequent assembly. In Arachne, the main idea is that a sequencing error reveals itself as a singleton base aligned to several other reads that all agree to a different base – in contrast to a repeat polymorphism, which should be shared by several reads. Euler's error correction is based on finding and modifying low-frequency words in the reads, and is generally more aggressive, resulting in a drastic reduction in the number of errors by as much as a factor of 50. After error correction, Arachne aggressively discards read-to-read overlaps that disagree in high-quality bases, because such overlaps are overwhelmingly likely to be repeat-induced. Most assemblers at this stage also discard likely *chimeric* reads, that is, reads that are formed by two distant segments of the genome being glued together. The signature of such reads is that they overlap other reads to the left and right, but no overlap spans the chimeric joint.

8. Contig layout

The prevailing way of representing all read overlaps is the *overlap graph* (Myers, 1995), where reads are nodes, and overlaps are labeled edges that contain information on the location and (optionally) quality of overlap. Only full overlaps between reads x and y are stored in the graph: partial overlaps that end somewhere within the two sequences are clearly repeat-induced and not stored in the graph. Repeat boundaries can be detected in an overlap graph by finding a read x that extends to two reads y and z to the left (or right), where y and z do overlap one another. The Celera assembler and Arachne use this overlap graph to merge reads into contigs up to the boundaries of repeats, thus joining all local interval subgraphs into contigs. To assemble contigs, Arachne employs a further heuristic: paired pairs of reads, defined as two plasmids of similar insert size with sequence overlaps occurring at both ends, are identified and merged, except under a heuristic condition that detects and avoids the instance of long repeats. Paired pairs help to cross high-fidelity repeats of length slightly longer than a read length. Phusion instead clusters the reads and then passes the clusters to local assembly calls to PHRAP. One advantage of this approach is the use of PHRAP for low-level assembly, because PHRAP has been highly tuned to work well with real data. Most assemblers use several additional heuristics during contig layout, in order to extend contigs as far as possible. For example, sequencing errors near the end of one read are identified as such by noticing that the read does not overlap any other read on that side. Contig breaks due to such sequencing errors are then crossed. Also, contig breaks due to repeats that are shorter than one read length are resolved by finding reads that span the different repeat copies. Precisely, a repeat can be resolved if each copy, except for at most one, is spanned by a read.

The resulting contigs constructed by Celera and Arachne are either unique, representing sequence that occurs once in the genome, or repetitive, representing a high-fidelity repeat sequence whose reads were merged together. In Arachne, the repeat has to exhibit nearly 100% fidelity. Contigs are classified as unique or

repetitive by measuring the density of reads within a contig: repetitive contigs are likely to be twice or more times as dense as unique contigs (Myers *et al*., 2000).

9. Supercontig layout

Once contigs are constructed and classified as unique or repetitive, the Celera and Arachne assemblers link them into larger structures, called *scaffolds* or *supercontigs*. One read-pair link can be an error, but two or more mutually confirming links that connect a pair of contigs are very unlikely by chance, and – in general – can be safely used to join the contigs into supercontigs. Most assemblers first join the unique contigs while excluding likely repeat ones to produce supercontigs that represent correctly ordered and oriented unique sequence with gaps. Then, gaps are filled by recruiting the repeat contigs. This last stage of repeat resolution is rather complicated, and involves a combination of several heuristic approaches. The Celera assembler fills in repeats in a series of increasingly aggressive steps by recruiting first repetitive contigs that contain two or more read-pair links to the flanking unique contigs, then those that contain one link and some sequence overlap, and finally the rest conditionally on some heuristics. Arachne attempts to walk through the gap between two unique contigs by a shortest-path search that requires anchors spaced at almost every 2 kb, where an anchor is a repetitive contig with read-pair links to the flanking unique contigs. This heuristic, in practice, results in a reasonably accurate repeat reconstruction, except in the case of high-fidelity tandem repeats, which are often collapsed and show up as deletions with respect to the true sequence.

10. Derivation of consensus sequence

Once a layout has been obtained, deriving consensus sequence is a relatively straightforward task. Starting from the leftmost read of each contig, consensus sequence is derived from the multiple alignment of reads. Conservative quality scores are given to each consensus base according to the quality and agreement of bases in the multiple alignment column. The Celera assembler will additionally report positions that appear polymorphic and give an estimate of the likelihood that the polymorphism is real versus repeat-induced.

11. Discussion on existing WGS assemblers

An elegant formulation of sequence reconstruction as an Eüler Path Problem on a de Bruijn graph (Pevzner, 1989), originally proposed in the context of sequencing by hybridization, has led to the development of the Eüler assembler (Pevzner *et al*., 2001). According to that approach, a graph is constructed whose nodes are the k-long words in reads and whose edges connect pairs of k-long words that share a $(k-1)$-long overlap. Read overlaps are thus implicitly found in an efficient manner

similar to Arachne's and Phusion's approach. Error correction is done directly on the k-long words by modifying words that are too infrequent. Assembly then reduces to finding the correct *Eülerian path* – there are usually a large number of Eülerian Paths. An Eülerian Path is a path that uses every edge exactly once. To achieve that, a series of graph simplifications are taken on the basis of the reads and the read-pair links. This approach has the advantage of clean formulation and demonstrably strong performance in resolving repeats – or identifying all assembly ambiguities due to repeats. One challenge is to develop an implementation that is efficient enough for whole mammalian genome assembly. The de Bruijn graph provides the same branching structure (repeat representation) as Myers's original overlap graph but at k-mer resolution rather than fragment resolution and provides more precise repeat boundaries at the cost of extra memory usage.

Several assemblers exist for large-scale application. The Celera assembler, Arachne, and Jazz effectively use the overlap-layout-consensus paradigm combined with read-pair information. Phusion follows a different approach, motivated by the fact that PHRAP is a well-tried and effective approach for small-scale assembly: Phusion first clusters the reads efficiently and then sends several local assembly problems to PHRAP. The assemblies are then merged and corrected according to read-pair information. Arachne and Phusion were both used for assembling the Mouse genome, with comparable performance (Jaffe *et al*., 2003; Mullikin *et al*., 2003). Atlas is a suite of programs for assembling a genome with an approach that combines clone-based and WGS data, and was used to assemble the rat genome (Rat Genome Sequencing Project Consortium, 2004).

12. Sequencing and assembly in the future

A few years ago, WGS assembly was considered impossible for large and repeat-rich genomes. Today, it is routinely applied, thanks to the development of computational methods led by the Celera assembly team and by public efforts. The success of WGS assembly contributed to the interest in bioinformatics methods within the biology community. Although the assembly research pertinent to current sequencing technology seems to be reaching diminishing returns, additional open problems are coming from the development of new and revolutionary sequencing technologies that promise to deliver the "$1000 genome" within a decade (**http://grants.nih.gov/grants/guide/rfa-files/RFA-HG-04-003.html**). Computationally, such technologies can be largely divided in two categories: (1) those that produce short, accurate reads cheaply, such as Pyrosequencing (Ronaghi *et al*., 1998; Ronaghi, 2001) or other technologies (Mitra and Church, 1999; Mitra *et al*., 2003; Braslavsky *et al*., 2003) and (2) those that produce very long reads, but potentially with very high error rates (see Pennisi, 2002). Short reads should be harder to assemble, even if the mate-pair information is available. The reason is, again, effective repeat content: fewer exact repeats will be completely spanned by a read length. However, if reads are clustered without sacrificing the method's speed and low cost (e.g., by following a random clone-based sequencing approach that does not involve physical mapping), assembly should be possible. Long reads will present interesting alignment and large-scale indexing

problems. In general, once the technological hurdles are overcome and a concrete computational problem is formulated, we can be confident that computational biologists will solve it and help ultimately make the $1000 genome a reality.

Specialist Review

Genome signals and assembly

Marek Kimmel
Rice University, Houston, TX, USA

1. Introduction

Sequencing of entire genomes of various organisms has become one of the basic tools of biology. However, quality of genome assembly depends to a large extent on the structure of genomic sequences, notably, signals such as repeats, polymorphisms, and nucleotide asymmetry as well as structural motifs such as protein motifs (*see* Article 28, **Computational motif discovery**, Volume 7), gene promoters, enhancers and suppressors (*see* Article 19, **Promoter prediction**, Volume 7 and Article 24, **Exonic splicing enhancers and exonic splicing silencers**, Volume 7), transcription factor binding sites, exon/intron splice junctions, regions of homology between sequences (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7), and protein docking sites. Probabilistic and statistical properties of the structural motifs are covered elsewhere in this volume (*see* Article 6, **Statistical signals**, Volume 7). We focus here on global features of genome assembly. The importance of these has been recognized in the book by Waterman (1995), in seminal papers of Lander and Waterman (1988) and Li and Waterman (2003), as well as in the book by Ewens and Grant (2001). Genome assembly can be modeled as a binomial/Poisson stochastic process. From the properties of this process, it is possible to derive the statistics of contig size and in this way to determine the coverage needed to achieve an assembly of desired quality. Analogously, probing the fragments with l-mers, it is possible to estimate the size of the genomic sequence, even when repeats are involved. This is accomplished by reconstructing the repeat structure, using an expectation-maximization algorithm. In the framework of this theory, it is also possible to estimate the total gap length and the stringency ratio.

In this review, we provide an account of these topics as well as of some other more specialized sequence signals such as polymorphisms, nucleotide asymmetry, and annotation by words. We also consider some real-life and made-up examples.

2. Statistics of genome assembly – contigs and anchors

The following account is mainly based on Ewens and Grant (2001), Chapter 5. If biological details are omitted, shotgun genome sequencing can be reduced to

assembly of a sequence of total length G, from N fragments (also called *reads*) of equal length L. Fragments are randomly selected from sequence G, and the assembly is feasible if there exists enough overlap between the fragments. To ensure this, the coverage $a = NL/G$ should be large enough and certainly greater than 1. Depending on the strategy used, G may represent the entire genome (WGS, whole genome shotgun) or a subset of the genome. In Figure 1, we depict an example, this one with incomplete coverage.

A model for the random fragments is the binomial/Poisson stochastic point process, in which the coordinates of the left ends of the fragments are independent random variables uniformly distributed over G. Neglecting boundary effects, we obtain that the probability that the number of fragments with left ends in the interval $(x, x-h)$ is equal to k and has distribution *binomial* $(N, h/G)$ or approximately *Poisson* (Nh/G). A union of overlapping fragments is named a *contig*. In order to obtain a good quality of assembly, it is necessary that the contigs cover as much of G as possible. Mean number of contigs is equal to

$$\begin{aligned} E(\text{ \#contigs }) &= N \times \Pr(\text{fragment is rightmost in a contig}) \\ &= N \times \Pr(\text{fragment does not include the left end of any} \\ &\qquad \text{other fragment}) \\ &= N \times \exp\frac{-NL}{G} = \frac{aG}{L} \times \exp(-a) \end{aligned} \tag{1}$$

Figure 2 depicts $E(\text{ \#contigs })$ as a function of coverage a. $E(\text{ \#contigs })$ first increases but then decreases back, since smaller contigs coalesce with increasing coverage. A single (length G) contig is expected when coverage reaches $a \approx 8$. Expected contig size can be expressed as

$$\begin{aligned} \mathrm{E}(S) &= \mathrm{E}(\text{\#fragments} - 1)\ \mathrm{E}(\text{inter} - \text{epoch distance}) + L \\ &= \frac{1-\exp(-a)}{\exp(-a)} \int_0^L x\lambda \frac{\exp(-\lambda x)}{1-\exp(-\lambda L)} \mathrm{d}x + L = L\ \frac{\exp(a)-1}{a} \end{aligned} \tag{2}$$

$E(S)$ increases as smaller contigs coalesce. For the data as in Figure 2, $E(S) = G$ is expected when coverage reaches $a \approx 8$.

We might require that the contigs be anchored, that is, each of them include at least one anchor, which is a genomic site of known location (an element of a

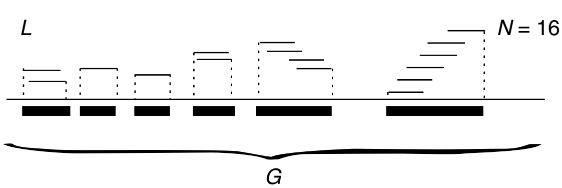

Figure 1 Schematic depiction of 6 contigs assembled from $N = 16$ fragments, of length L each, of genomic sequence of length G

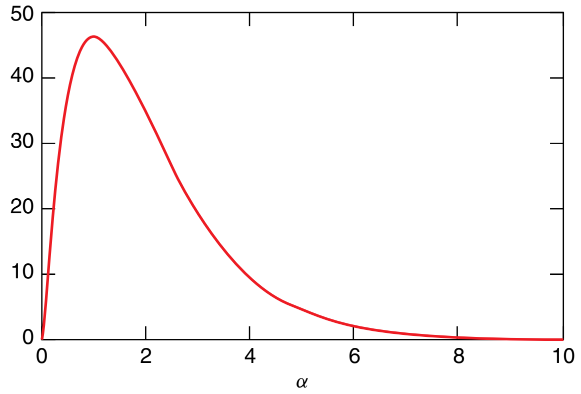

Figure 2 Expected number of contigs as a function of coverage a. Parameter values, $L = 800$, $G = 100\,000$

gene map). Let us define the coverage with M anchors as equal to $b = ML/G$ and suppose that the anchors follow the binomial/Poisson process. Then, we have

$$\text{E(\# anchored contig)} = Nb\,\frac{\exp(-a) - \exp(-b)}{b - a} \tag{3}$$

which is reduced to the nonanchored case as $b \to \infty$, but usually is smaller.

3. Gap statistics

In a recent paper, Wendl and Yang (2004) discuss prediction of the size of gaps in WGS projects. According to the Lander and Waterman (1988) theory, the expected number of gaps is equal to

$$E = N \exp[-\alpha(N - 1)] \tag{4}$$

where $\alpha = (L - T)/G$ is the effective fractional read (fragment) length, with T being the minimum overlap required. Maximum gaps number consequently is equal to

$$E_{\max} = \frac{\exp(\alpha - 1)}{\alpha} \tag{5}$$

Lander and Waterman (1988) theory also implies that stringency σ, that is, the proportion of existing gaps to the expected maximum, can be expressed by the effective coverage $\delta = N(L - T)/G$, as $\sigma = E/E_{\max} = \delta \exp(1 - \delta)$. Wendl and Yang (2004) proceed to demonstrate that these expressions underestimate stringency (as it was claimed earlier on) and provide semiempirical estimates of stringency, given coverage, $\sigma_{\text{emp}} = 1.187 \exp(-0.334\delta)$ for eukaryotes and $\sigma_{\text{emp}} = 0.701 \exp(-0.211\delta)$ for prokaryotes. These estimates were obtained by applying linear regression to log-linearized data from 20 WGS assemblies. Empirical stringencies

were computed as the quotients of the numbers of gaps in the assembly and a theoretical maximum, while the coverages were based on the numbers of reads in an assembly (further details in Wendl and Yang, 2004).

4. Repetitive elements and estimation of genome length

Repetitive elements are among the most frequent dynamic features of the genome. Many of them display complicated evolutionary dynamics (for some models, see e.g., Kimmel and Axelrod, 2002). Here, mostly based on Li and Waterman (2003), we review the influence of repetitive elements on estimation of genome length. In the shotgun sequencing method, the genomic sequence is assembled from overlapping fragments. Uncertainties of the assembly (see further on) lead to the need to analyze the repeat structure of the sequence to be able to estimate the true size of the genome or its fragment sequenced. Indeed, let us consider a given DNA sequence. If we can choose l such that almost all l-mers appear only once in the sequence, if they appear at all, then, by counting how many different l-mers there are in the fragments, we can have a good estimate of the length of the sequence. This is accurate, assuming that the sequence is random with letters generated independently. However, there may be many repeats in the sequence (Primrose, 1998), such that many l-mers appear in it twice or more, even if l is quite large. In this case, the number of different l-mers in the fragments should be much smaller than the number of nucleotides in the sequence. However, if we know how many times each l-mer is repeated, and what fraction of the sequence it accounts for, we can estimate the sequence length. That is, we may have to estimate the repeat structure and coverage in order to estimate the sequence length.

Recall that, for an l-mer appearing in a sequence, instead of the number of this l-mer's occurrences in this sequence, we obtain the number of this l-mer's occurrence in N fragments. Because the fragments are randomly chosen from clone libraries, their positions in the original sequence are random, as is the number of occurrences of any l-mer in the sequence. Let us consider the distributions of these random variables first. Assume we know the coverage a of the genome by these N fragments. Also assume that an l-mer in the sequence cannot appear twice or more in any fragment, that is, any two copies of an l-mer are at least L base pairs apart in the original sequence. For a given l-mer, for instance, w, that appears in the sequence $n(w)$ times, how many times will it appear in N fragments?

Assume $x_i(w)$ is the number of fragments that cover the ith copy of w, in which i is from 1 to $n(w)$. Then, w appears $x_{n(w)}(w)$ times in the fragments. Note that $x_i(w)$, $i = 1, \ldots, n(w)$ are independent identically distributed (i.i.d.) and approximately Poisson. Assume the parameter of the Poisson process is λ

$$\lambda = \frac{N}{G - L + 1} \tag{6}$$

(Lander and Waterman, 1988). The distribution of $x_1(w)$ is Poisson with parameter $\lambda\,(L - l + 1)$. Owing to the additivity of Poisson process, the distribution of $x(w)$

is Poisson with parameter $n(w)\ \lambda\ (L - l + 1)$. For any given l-mer w in the sequence, we do not have a vector of $\{x_i(w), i = 1, \ldots, n(w)\}$, but $x(w)$, the sum of the elements in the vector. For estimation, we can use all observations from those l-mers, that appear approximately $n = n(w)$ times in the original sequence, as samples of w (family n). Recall that the number of occurrences of those l-mers may not be independent, although they have the same distribution. Assume w_1, $w_2, \ldots, w_m$ are those family n l-mers. We have

$$\frac{x(w_1) + \cdots + x(w_m)}{m}$$

approach $n(w)\ \lambda\ (L - l + 1)$ when m is large.

Assume there are k families of l-mers in the original sequence, the number of occurrences of any l-mer in the fragments from the ith family is a Poisson random variable with parameter $a_i\, a$, in which $a = \lambda\ (L - l + 1)$ is the coverage and a_i is an unknown integer. Different l-mers in the ith family account for $\alpha_i \times 100\%$ of all different mers in the original sequence. Mathematically, we have a set of samples from a mixture of Poisson distributions, and some of the samples are dependent. We estimate a_i, α_i, and a for $i = 1, 2, \ldots, k$. For this mixed-Poisson proportion problem, we get the following expressions (Lange, 1998)

$$a_i a = \frac{\sum_w n(w)\,\Pr(w \in \text{family } i|n(w))}{\sum_w \Pr(w \in \text{family } i|n(w))}$$

$$\alpha_i = \frac{\sum_w \Pr(w \in \text{family } i|n(w))}{\sum_{j=1}^{k} \sum_w \Pr(w \in \text{family } i|n(w))}$$

$$\Pr(w \in \text{family } i|n(w)) = \frac{\alpha_i}{\sum_{j=1}^{k} \alpha_j \left(\frac{a_j}{a_i}\right)^{n(w)} \exp[(a_i - a_j)a]} \tag{7}$$

We have no data for w with $n(w) = 0$. That is, we do not know group 0 if we assume that there are group i-mers in the sequence, which appear i times in the fragments, for $i = 0, \ldots, groupNum$. But, we can use the following formulas to estimate group 0.

$$group(0) = \frac{\sum_{i=1}^{k} \alpha_i \exp(-a_i a) \sum_{i=1}^{groupNum} group(i)}{\sum_{i=1}^{k} \alpha_i (1 - \exp(-a_i a))} \tag{8}$$

According to Li and Waterman (2003), the length of the sequence is estimated by the second or third expression below.

$$\text{percentage of the tuples from the } i\text{th family} = \frac{\alpha_i a_i}{\sum_{j=1}^{k} \alpha_j a_j}$$

$$\text{length of the sequence} = \sum_{j=1}^{k} \alpha_j a_j \sum_{j=1}^{groupNum} group(j) \tag{9}$$

or

$$\text{length of the sequence} = \frac{N(L-l+1)}{\min\{a_j a : j = 1, \ldots, groupNum\}} \tag{10}$$

The expressions developed can be used to create a recursive algorithm of the Expectation-Maximization (EM) type. This first entails setting a large number for k and a proper number for l and calculation of $group(j)$, for $j = 1, 2, \ldots, groupNum$, based on data. Then, we set initial values for a_{i}, a, and α_{i}, respectively for $i = 1, 2, \ldots, k$. Subsequently, we compute $group(0)$ and new values for a_{i}, a, and α_{i}, respectively for $i = 1, 2, \ldots, k$, based on the expression above. We repeat this step until convergence is reached. Finally, we calculate the percentage of each family of substrings and the length of the sequence.

The proper choice of l is critical for the functioning of the method. As stated above, we should let l be large enough so that many l-mers in the original sequence are unique l-mers. That is, when the DNA is G base pairs (bp) long, l should satisfy $4^l > G$ if the sequence is generated from a uniform i.i.d. mechanism. On the other hand, we cannot let l be too large. For instance, if we let $l = L$, then there are N l-mers in all, and each l-mer appears once in the fragments in general. Then, our estimate of a is 1, which is incorrect. Moreover, the larger l is, the fewer the number of samples, and the less accurately we can estimate a_i, a, and α_{i}, for $i = 1, 2, \ldots, k$. Therefore, l must be large, but not too large. Further details can be found in Li and Waterman (2003).

Statistical properties of this algorithm do not seem to be well developed. Estimation of $group(0)$ is based on the Poisson assumption. Figure 2 of Mullikin and Ning (2003) shows a frequency graph of the 17-mer word occurrence, based on mouse $a = 7.5$ assembly. It shows a large excess of single-occurrence words above the model curve, indicating that these words are bad data resulting from sequencing errors.

5. Examples of estimation of repeat structure and genome length

Li and Waterman (2003) provide examples of how their method functions. Their Example 3 assumes $G = 80\,000$, $L = 500$, and $a = 3$. There are two families

of repeats. One is 6-kb long with 2 copies, whereas the other is 1-kb long with 12 copies. Repeats appear in tandem in the original sequence. In more than 95% of the simulations, they observed that the estimated genome length is 73 104 bp; the estimated coverage is 3.283; the unique sequence accounts for 82.7% of the genome. There is only one family of repeats, which has 12 copies and accounts for 17.3% of the sequence. This example illustrates difficulties inherent when short genomes and low coverages are considered. Further details are discussed in Li and Waterman (2003).

6. Polymorphisms

The following is mostly based on Fasulo *et al*. (2002). Polymorphisms are differences in variants of DNA sequences present in different individuals and on paternal and maternal chromosomes in a single individual. Most algorithms for large-scale DNA assembly make the simplifying assumption that the input data is derived from a single homogeneous source. Frequency of polymorphisms (single nucleotide polymorphisms (SNP), variable-length microsatellites or block insertions and deletions (indels)) depend on the evolutionary history of the species. For example, indels are twice as frequent in the human genome than in the *Drosophila* genome. Discrepancies due to polymorphisms will cause false negatives in the overlap relations among fragments and may result in confusing the polymorphisms with evolutionary divergence in repeat regions of the genome. The Celera Assembler (Myers *et al*., 1995) includes the A-statistic, which can help determine if the region containing the bubble seems repetitive. A sequence of overlapping fragments (for simplicity assumed to have equal lengths) of a genomic sequence can be depicted using a directed graph, which is linear for an unambiguous complete assembly. Polymorphisms will be represented as bubble-like structures (for examples, see Fasulo *et al*., 2002). Bubbles can be resolved in two ways: (1) A single path through the bubble can be designed, resulting in a consensus sequence. (2) Multiple alternative paths may be accepted and represented in the final assembly. An algorithm for bubble resolution (smoothing), which is a subroutine of the Celera Assembler, is described in Fasulo *et al*. (2002). The final validation of bubble smoothing is resequencing of the putative polymorphisms.

7. Bias in AT versus GC composition

It is known that high AT contents of the genome degrades the quality of assembly. Wendl and Yang (2004) provide a semiempirical relationship for stringency in prokaryotes $\sigma_{\text{emp}} = 1.129\exp(-4.93\gamma)$, where γ is the GC content, with correlation of around 76%. Analogous relationship in eukaryotes is not so well defined.

8. Annotation by words and comparison of genome assemblies

It is possible to annotate large genomic sequences with exact word matches. Healy *et al*. (2003) developed a tool for rapidly determining the number of exact matches

of any word within large, internally repetitive genomes or sets of genomes. This is achieved by creating a data structure that can be efficiently queried and that can also entirely reside in random access memory (RAM). The solution depends upon the Burrows–Wheeler transform, a method used to create a reversible permutation of a string of text that tends to be more compressible than the original text (Burrows and Wheeler, 1994). First, given a genome **G** of length G, we create a new string **G**$ of length $G + 1$ by appending a "$" to the end of that genome. We then generate all $G + 1$ "suffixes" of **G**$, that is, substrings that start at every position and proceed to the end. We next associate with each suffix the letter preceding it. In the case of the suffix that starts at the first position, we associate the new $ character and assume that "$" has the lowest lexicographical value in the genome alphabet. The string of antecedent letters, in the lexicographical order of their suffixes, is the Burrows–Wheeler transform of the G$ string. For example, if the genome were simply "CAT", the G$ string would be "CAT$". Then the suffixes of the genome in sorted order would be: "$", "AT$", "CAT$", and "T$". The Burrows–Wheeler transform of this particular G$ would be the letters that precede each of these suffixes taken in the same order, specifically "TC$A". The list of pointers taken in the order of the sorted suffixes would be (3,1,0,2). This list of pointers is the suffix array for the string "CAT$". The suffix array for the human genome approximately constitutes 12 Gb (3 billion, 4-byte integers) of RAM. However, the B–W string alone is sufficient to determine word counts and it can be compressed to about 1 Gb of RAM. Furthermore, for querying, all but a negligibly small portion of the compressed form can remain so throughout execution (Healy *et al*., 2003).

Using the above tools, any region of the genome can be annotated with its constituent mer frequencies. Healy *et al*. (2003) have depicted annotations of a 5-kb region of chromosome 19 four-mer lengths, 15, 18, 21, and 24 bases. For each coordinate and each word length, they determined the count of the succeeding word of the given length, in both the sense and antisense directions. One of the most striking features of this terrain is the presence of narrow spikes in 15-mer counts. This is a virtually universal property of all regions of the human sequence examined, including coding exons and it is statistically significant (based on a comparison with random genomes). Hypothetically, these spikes might result from the accidental coincidence of 15-mers in ordinary sequence with 15-mers present in high-copy-number repeats.

Another application of the method was to monitor successive human genome assemblies. Healy *et al*. (2003) compared December 2001 and June 2002 assemblies and found that, unexpectedly, 1.2% of their probe words vanished from the June 2002 assembly (i.e., all of their constituent 21-mers went from copy number one in their original assembly, to copy number zero in a subsequent assembly). Systematic studies revealed both losses and gains of single-copy words between assemblies. Although there may be technical reasons explaining the dropout of some of these fragments, such as difficulty in assembly or poor-quality sequence, it is also likely that, due to insertion/deletion and order-of-sequence polymorphisms in humans, no fixed linear rendition of the genome is feasible. A detailed discussion is provided in Healy *et al*. (2003).

9. Examples

The following examples illustrate the complex nature of global-level organization of human chromosomes and demonstrate that the theory developed above is important for the applications. Recently, edited sequences of human chromosome 14 and of the male-specific region of chromosome Y (MSY) were published (Heilig *et al*., 2003; Skaletsky *et al*., 2003). In chromosome 14, an ancient duplication involving 70% of chromosome 14 and a portion of chromosome 2 has been reported. This event is, however, only visible at the protein level and predates the mouse – human separation. Heilig *et al*. (2003) found that 1.6% of chromosome 14 consists of interchromosomal segmental duplications contained in fragments of 1 kb or more that show at least 90% sequence identity. On the basis of further references in Heilig *et al*. (2003), comparable value, based on a different comparison procedure, was reported earlier, and confirms that chromosome 14 has the lowest content of interchromosome segmental duplications in the human genome. In a similar analysis that excluded repetitive DNA, it was found that internal duplications account for 1.1% of chromosome 14 and are clustered in four segments. The largest includes an 800-kb region adjacent to the centromere, which is also part of the segmental duplication shared with chromosome 22.

The male-specific region of the Y chromosome, the MSY, differentiates the sexes and comprises 95% of the chromosome's length. Skaletsky *et al*. (2003) determined, among others the most pronounced structural features of the ampliconic regions of Y are eight massive palindromes. In all eight palindromes, the arms are highly symmetrical, with arm-to-arm nucleotide identities of 99.94–99.997%. The palindromes are long, their arms ranging from 9 kb to 1.45 Mb in length. They are imperfect in that each contains a unique, nonduplicated spacer, 2–170 kb in length, at its centre. Palindrome P1 is particularly spectacular, having a span of 2.9 Mb, an arm-to-arm identity of 99.97%, and bearing two secondary palindromes (P1.1 and P1.2, each with a span of 24 kb) within its arms. The eight palindromes collectively comprise 5.7 Mb, or one-quarter of the MSY euchromatin.

In addition to palindromes and inverted repeats, the ampliconic regions of Yq and Yp contain a variety of long tandem arrays. Prominent among these are the newly identified NORF (no long open reading frame) clusters, which in aggregate account for about 622 kb on Yp and Yq, and the previously reported TSPY (testis specific protein Y) gene clusters, which comprise about 700 kb of Yp. The NORF arrays are based on a repeat unit of 2.48 kb. Numerous further structural features of MSY and their evolutionary explanations, are discussed in Skaletsky *et al*. (2003).

10. Concluding remarks

As more and more genomes become sequenced, structural features such as repeated regions, short repeats (mini- and microsatellites), palindromes, and polymorphisms are emerging (for the human Y chromosome example, see Skaletsky *et al*., 2003). Current understanding of genome assembly has been dominated by practical

considerations. In particular, sequencing is time consuming and constrained by cost-efficiency. However, shotgun sequencing also is a stochastic procedure and therefore even edited genome assemblies may contain inaccuracies (Healy *et al*., 2003). On the other hand, stability of a genome as a whole is not a priori known and may be less perfect than expected (Healy *et al*., 2003). These observations underscore the need for methods, such as Li and Waterman (2003) algorithm, to estimate structural features of the genome on the basis of reads available. More generally, further mathematical work seems to be needed, transcending the existing theory (see, e.g., Lander and Waterman, 1988), to understand the uncertainties of genome assembly.

Microbial sequence assembly

George Weinstock
Baylor College of Medicine, Houston, TX, US

The first microbial genome projects began in the 1990s and focused either on important model systems (e.g., *Escherichia coli*, *Saccharomyces cerevisiae*) or on important pathogens (e.g., *Mycobacterium tuberculosis*). The prevailing view for these early microbial projects was that assembling the complete genome sequence must be piecemeal from large insert clones such as cosmids that were ordered into a tiling path along the chromosome (*see* Article 8, **Genome maps and their use in sequence assembly**, Volume 7). Each large insert clone would be sequenced by shotgun sequencing and its sequence assembled on the basis of sequence overlaps between the individual random shotgun reads. The assembled large insert clones would then be stitched together to form the complete genome.

The alternative assembly method to this clone-by-clone (CBC) approach was whole-genome shotgun (WGS) assembly, where the entire genome would be fragmented and cloned and the ends of each clone would be sequenced to produce a large amount of random sequence reads. These would then be assembled en masse to produce the final assembly. However, in the early years of microbial genome projects, the CBC approach was broadly adopted out of a concern that repeated sequences in the genome would pose an insurmountable problem for the WGS approach. The repeated sequences could not be unambiguously placed on the basis of sequence overlaps, and would therefore create gaps in the genome assembly.

The concern for the repeated sequence problem was dramatically shattered with the assembly of the *Haemophilus influenzae* genome using the WGS method at The Institute for Genomic Research in 1995 (Fleischmann *et al*., 1995). This was the first large-scale (for microbes) WGS project to be completed and set the stage for virtually every subsequent microbial genome project. The software developed for this project, the TIGR assembler (Pop and Kosack, 2004), had many ideas that are used in latter day genome assembly programs, even though the assembly software has grown in sophistication and now handles genomes over 1000 times the size of a bacterium.

The general approach used in most WGS genome projects nowadays is to first create a series of shotgun genomic libraries representing clones with different insert sizes (usually small, 3 kb, medium, 10 kb, and large, 40 kb). Both ends of each clone are sequenced until the total number of bases produced is about eight times the number of bases in the genome. The reads are then assembled on the basis of sequence overlaps between reads to produce contigs: blocks of contiguous sequence

representing a path of overlapping reads. Contigs end, however, resulting in a gap. The gaps may be due to regions that are missing from the clone libraries, or regions containing repeated sequences that cannot unambiguously be placed in the genome and so are skipped by the assembly software.

The contigs that result from assembling the WGS reads are ordered and oriented with respect to each other using read pair (sometimes called mate pair) information. Each clone in the shotgun libraries was sequenced from both ends, resulting in a pair of reads separated by a distance in the genome equal to the insert size of the clone. This information is used to link contigs together when the reads in a pair fall in different contigs. Contigs that are linked by read pairs are often called scaffolds. Thus, most assembly algorithms deal with the automated construction of contigs and scaffolds.

At this stage of the assembly, there are two kinds of gaps remaining to be filled: gaps between contigs within a scaffold (captured gaps since clones exist that span them) and gaps between scaffolds (uncaptured gaps). In the former case, the polymerase chain reaction is used to generate a product spanning the gap, since primers can be designed and properly oriented on the basis of the sequence of the contigs flanking the scaffold. The latter case poses the greatest challenge since one does not know which contigs flank uncaptured gaps. The principal solution to sequencing these regions is primer walking, where a primer is made from the end of a contig adjacent to a gap and used to sequence from the genome into the gap region. This new sequence either connects the contig to scaffold or, if not, it is used as the target for the design of a new primer and another walk is made. The process is repeated until the gap is spanned.

The gap-filling steps just described tend to be more labor-intensive and costly than the WGS sequencing and automated assembly stages. In fact, the major advantage of the WGS approach is that there is no need for up-front efforts to map large insert clones or develop a tiling path. As a result, a WGS genome project may stop after automated assembly and before the gap-filling stage. The product of such a project is called a "draft" genome sequence. In the contigs, the sequence is of generally high quality and sufficient for gene predictions or design of microarrays, which are often the main deliverables from a genome sequence. The gaps that remain may principally be due to repeated sequences that are often not critical in understanding the phenotype of an organism. Draft sequencing is particularly popular for genomes where gap filling is difficult due to the large size of a genome or other properties. However, a "finished" genome sequence, one with gaps filled and other defects removed, is still superior for detailed analysis of genes and regulatory sequences, where single nucleotide differences can be significant.

Short Specialist Review

Comparative analysis for mapping and sequence assembly

Aleksandar Milosavljevic
Baylor College of Medicine, Houston, TX, USA

1. Comparative analysis for mapping and sequence assembly

Comparisons of mammalian genomic sequences reveal extensive similarity at both the chromosome and basepair levels (Mouse Genome Sequencing Consortium, 2002; Rat Genome Sequencing Project Consortium, 2004). The increasing number of assembled reference sequences produced by ongoing genome sequencing projects thus provides information that is potentially useful for the mapping and assembly of related genomes.

Detection of unique orthologous sequence fragments, which are sometimes referred to as "orthologous anchors" or "syntenic anchors", is a key step in many comparative genomic methods (Mural *et al*., 2002). The density of anchor sequences and the conservation of their relative order, orientation, and distances is a key indicator of utility of comparative information for mapping and assembly of one organism using the assembled sequence of a related organism as a template.

2. Detection of orthologous anchors

Orthologous anchors may be identified by comparing two assembled genomes, one assembled genome against an extensive collection of contigs from another genome, or by comparing contigs from two partially assembled genomes. (The word "contig" here refers to either to a group of contiguous assembled sequencing reads or to a single read.)

On one hand, the comprehensive nature of all-against-all sequence comparisons of two genome-scale databases is computationally demanding. On the other hand, it allows identification of truly orthologous anchors with high specificity via the application of a reciprocal best match filter (Mural *et al*., 2002).

The most widely used comparison programs are optimized for fast and sensitive comparison of short queries against a single large database (Altschul *et al*., 1997; Pearson, 2000). In contrast, for maximum utility of a "reciprocal best match" filter, anchoring ideally requires simultaneous comparison of genome-sized databases. A new generation of comparison programs employ various types of genome-scale

indices that are designed to fit within computer memory (RAM), which provides the speed required for genome comparison (Ning *et al*., 2001; Kent, 2002; Ma *et al*., 2002; Kalafus *et al*., 2004). One of these programs was specifically designed for the anchoring task (Kalafus *et al*., 2004).

3. Comparative mapping of reads and contigs

Anchoring of contigs from one species onto an assembled genome of the other related species provides hypothetical order, orientation, and distance information. This information can be independently confirmed by a variety of methods. For example, mate-pair reads obtained from both ends of clone inserts of known size may bridge the gap between two anchored contigs, thus confirming their putative distance and orientation. Anchored contigs may also be bridged computationally from the read overlap graph by constructing a tiling path of overlapping reads. Alternatively, the bridging may be performed by targeted experiments, such as PCR and primer walking.

There are two general contig mapping scenarios. The first scenario involves one assembled genome and the contig set from another, partially assembled genome (Pletcher *et al*., 2001). The second scenario involves two genomes assembled at the contig level only, each providing only fragmentary information for bootstrapping each other's assembly. The algorithmic challenge inherent in the latter method has recently been addressed (Veeramachaneni *et al*., 2003).

4. Comparative mapping of clones

A variety of methods exists for mapping cloned genomic fragments, such as Bacterial Artificial Chromosomes (BACs), of one species onto an already assembled genome of another. The information may be either used to select clones for targeted comparative sequencing or to infer their hypothetical order, overlap and distance, or for both purposes.

One method for comparative physical mapping starts with a comparison of already assembled genomes to identify regions generally conserved across species. The conserved regions are then used to design hybridization probes for identification of homologous clones from third species. Key assumption is that the sequence conservation between two species is a good indicator of its conservation in the third, related species. The method has been applied to the construction of orthologous clone–contig maps in multiple species (Thomas *et al*., 2002).

A more direct probe design requires whole-genome shotgun reads from the mapped species. Reads anchored onto an assembled genomic sequence of a related species can be used as intraspecies hybridization probes to identify clones that map onto the anchoring sites. A large collection of mouse BACs has been mapped onto the human genome by this method (Thomas *et al*., 2000).

An even more direct comparative clone mapping method involves sequencing of clone ends and their anchoring onto the related genome. A clone is mapped by this method if the distance between the two anchoring sites approximates

clone insert size. Recent large-scale applications of this method involved BAC end sequencing (BES) of large collections of chimpanzee (Fujiyama *et al*., 2002) and bovine (Larkin *et al*., 2003) BACs and their mapping onto the assembled human genome.

Finally, recently proposed Pooled Genomic Indexing (PGI) method (Milosavljevic *et al*., 2005; Csuros and Milosavljevic, 2004) maps BACs of one species onto the genome of another by shotgun sequencing of BAC pools. Pools are designed so that two pools have at most one BAC in common. Consequently, if reads originating from two pools anchor within the same BAC-sized genomic location of a related genome, the BAC that is present in both pools is mapped onto that location. PGI has the potential to achieve significant reduction in cost and efficiency of comparative mapping. In a first genome-scale application of PGI, a library of rhesus macaque BACs is being mapped onto the human genome (Milosavljevic *et al*., 2005 #716).

5. Comparative sequence assembly

Assembled genomic sequence of one species can be used as a template to guide the assembly of another, related species. In contrast to the independent assembly, where only read overlap information is utilized in the assembly process, comparative assembly maximizes both read overlap and similarity of the newly assembled sequence to a reference template (Milosavljevic, 1999). An information-theory argument shows that the comparative information enables better detection of conserved regions than the comparison of independently assembled genomes (Milosavljevic, 1995).

Comparison of independently assembled genomic sequences frequently results in differences due to either evolutionary rearrangements or to assembly errors. Detection of the assembly errors leads to an improved assembly (Pletcher *et al*., 2001; Rat Genome Sequencing Project Consortium, 2004). To avoid assembly errors from occurring in the first place, comparative information may be employed earlier in the assembly process. Ideally, the comparative information is employed so as to simultaneously improve both the extent and quality of assembly.

Selection of appropriate comparative assembly strategy depends on specific circumstances. For example, if the genome in question has been covered by shotgun reads, comparative information may be employed in order to localize the assembly process. Specifically, some of the reads are first directly anchored onto their orthologous locations in the reference genome. The anchored reads are then used as “baits” to “fish out” some of the remaining nonanchored reads using intraspecies read overlap information, thus increasing the number of localized reads. Finally, the localized reads are locally assembled. Localized assembly process improves the extent and quality of assembly at low read coverage, particularly in the presence of repetitive elements.

Human genomic sequence has been used as a reference for the initial assembly of genomes of the mouse and dog (Abbott, 2000; Kirkness *et al*., 2003). A published NIH report anticipates that primate genome sequencing projects will be greatly aided by the availability of the finished human genome (NIH-NCRR, 2001). A

comprehensive pipeline for comparative assembly of bacterial strains has been recently developed (Pop, 2004 #740).

6. Comparative assembly of transcribed sequences

Expressed sequence tags (ESTs) obtained from sequencing cDNA clones can be assembled into transcript sequences using an assembled genomic sequence as a reference. In addition to their inherent biological significance, assembled transcript sequences have utility for the design of gene expression probes. Specifically, human EST fragments can be grouped using human genomic sequence and then locally assembled for the purpose of designing oligonucleotide probes for the analysis of gene expression.

7. Significant trends in sequencing technology

In contrast to the current applications of comparative sequence assembly, which are driven by the availability of assembled genomes, early applications were driven by necessity: short sequence fragments detected by hybridization technology could not be assembled independently and comparative assembly provided the solution (Milosavljevic, 1995; Milosavljevic, 1999). With the advent of DNA chip technologies, comparative sequencing using hybridization probes is now expanding to the genome scale (Frazer *et al*., 2001; Frazer *et al*., 2003).

New sequencing technologies have the potential to increase the throughput and decrease the cost of sequencing by orders of magnitude. These trends may lead to the expansion of the applications of sequencing in the same way that the increased performance and decreased cost of microprocessors expanded the applications of computing. One of the obstacles for wide adoption of the new technologies, such as pyrosequencing (Ronaghi, 2001), single molecule array-based sequencing (*see* Article 7, **Single molecule array-based sequencing**, Volume 3), massively parallel genome sequencing, and Real-time DNA Sequencing (*see* Article 8, **Real-time DNA sequencing**, Volume 3), is higher sequencing error rate and significantly shorter read length compared to the standard Sanger method. Such sequence fragments tend to be too short for independent assembly, particularly in view of the repeat-rich nature of mammalian genomes (*see* Article 2, **Algorithmic challenges in mammalian whole-genome assembly**, Volume 7) but they are long enough for the sort of anchored comparative mapping and assembly described above.

8. Summary

Comparative information has the potential to both decrease the cost and accelerate mapping and sequencing projects by reducing experimental effort. Various comparative mapping and sequencing methods have already been put in practice. Future demand for comparative mapping and assembly is likely to be driven

by two trends: the increasing availability of reference genomes as potential templates for assembly and advances in sequencing technology. If current trends continue, comparative assembly of individual human genomes and even diagnostic sequencing of individual tumor samples will become a routine practice.

A number of challenges will have to be overcome along the way to efficient gigabase-scale sequence assembly. One is the development of computational means for fast and accurate sequence anchoring based on all-against-all comparisons of exponentially increasing sequence databases. Another significant challenge is the development of comparative mapping and assembly methods and their systematic characterization and validation.

Short Specialist Review

Statistical signals

Andrew J. Gentles and Samuel Karlin
Stanford University, Stanford, CA, USA

1. Introduction

Detection of statistical signals in protein and DNA sequences is often a powerful method for uncovering biological significance and function. Examples of sequence features that can be identified through their statistical properties include protein motifs (*see* Article 28, **Computational motif discovery**, Volume 7), gene promoters, enhancers and suppressors (*see* Article 19, **Promoter prediction**, Volume 7 and Article 24, **Exonic splicing enhancers and exonic splicing silencers**, Volume 7), transcription binding sites, exon/intron splice junctions, regions of homology between sequences (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7), and protein docking sites. Each generally possesses some unique statistical property, or signal, that distinguishes it from other sequence segments. Signals may be interesting in their own right but are often combined in algorithms such as multiple alignments, homology detection, and gene finding (*see* Article 13, **Prokaryotic gene identification *in silico***, Volume 7, Article 14, **Eukaryotic gene finding**, Volume 7, Article 20, **Operon finding in bacteria**, Volume 7, Article 21, **Gene structure prediction in plant genomes**, Volume 7, Article 25, **Gene finding using multiple related species: a classification approach**, Volume 7, and Article 27, **Gene structure prediction by genomic sequence alignment**, Volume 7).

2. Maximal aggregate scoring segments

Central to identification of statistically significant signals, either in individual sequences or when comparing a group of sequences, is the general scoring scheme (Karlin and Altschul, 1990). Given a score defined on individual letters of a sequence (e.g., the amino acid substitution matrices BLOSUM62 and PAM120, commonly used in sequence alignment; for recent developments, see Yu *et al*., 2003), the general problem is to determine the statistical significance of a sequence region exhibiting a high aggregate (additive) score. Let S be a sequence composed of letters from an alphabet $A = \{a_1, a_2, \ldots, a_r\}$ that are independently randomly

distributed with probabilities $\{p_1, p_2, \ldots, p_r\}$. For each letter in S, one can associate a score s_i (e.g., the score for a matching letter in another sequence). In general, we are interested in finding the segment of the sequence that has the maximum aggregate score. Two important conditions are applied. First, we require that at least one score be positive. Second, we require the expected score per letter, $E = \sum p_i s_i$, be negative. If E were positive, the maximal segment would tend to be the whole sequence. The maximal aggregate scoring segment M_n in a sequence of length occurs with probability given by

$$\text{Prob}\left\{M_n \geq (\ln n)/\lambda^* + x\right\} \approx 1 - \exp\left\{-K^* e^{-\lambda^* x}\right\} \tag{1}$$

where λ^* is the unique positive solution of $\sum_{i=1}^{r} p_i e^{\lambda^* s_i} = 1$, and K^* is determined from a rapidly convergent series (see Karlin and Altschul, 1990). This approach can be extended to allow for neighbor dependencies (e.g., Markov models), as well as random and vector scores. To use the maximal scoring formulas, one chooses a significance level p (e.g., $p = 0.001$) and solves for $x = x(p)$ so that a segment score exceeding $(\ln n)/\lambda^* + x(p)$ is significant at the p level. The homology search algorithm, BLAST applies the ideas of maximal aggregate score to find matching sequence blocks between query and database sequences (Altschul *et al*., 1997).

For example, consider the case of aligning two sequences where gaps are not allowed (Dembo *et al*., 1994). The first sequence is composed of letters a_i with probability p_i, and the second sequence of letters a_j with probability p'_j, so that the pairing of a_i with a_j occurs with probability $p_i p'_j$. Assuming that the average pair score $\sum_{i,j} p_i p'_j s_{ij}$ is negative, then λ^* is the unique positive solution of $\sum_{i,j} p_i p'_j \exp\{\lambda^* s_{ij}\} = 1$. If the sequence lengths m and n grow at roughly similar rates, then equation (1) holds for the maximal scoring segmental alignment with n replaced by mn:

$$\text{Prob}\left\{M > \frac{\ln nm}{\lambda^*} + x\right\} \approx K^* \exp\left\{-\lambda^* x\right\}. \tag{2}$$

In other words, the alignment of two sequences has an unusually high (statistically significant at the $p = 0.01$ level) score if M exceeds $(\ln nm)/\lambda^* + x_0$, with x_0 determined so that $K^*\exp\{-\lambda^* x_0\} = 0.01$. The number of "separate" high-scoring segments is close to a Poisson distribution with parameter $K^*\exp\{-\lambda^* x_0\}$. This distribution can be used to estimate whether the number of high-scoring segments over a whole protein is unusually high. The theory readily generalizes to the case of multiple sequence alignments (Dembo *et al*., 1994).

The above results can be used in discriminating among possible scoring schemes. Suppose that $\{p_i\}$ are the overall letter frequencies in some random reference sequence. Now, let $\{q_i\}$ be desirable *target frequencies* that correspond to known representatives of some type of protein sequence that we wish to identify. Then, in a high-scoring segment, $q_i \approx p_i \exp\{\lambda^* s_i\}$, and appropriate scores are naturally defined as $s_i = \ln(q_i/p_i)$, With these log ratio scores, the mean score for a sample letter is automatically negative. The PAM and BLOSUM matrices are examples of natural log odds ratio score matrices.

3. Significant segment pair alignments (SSPA)

Most measures of similarity between protein sequences are local. One way to score global similarity between two protein sequences A and B is as follows: determine all high-scoring sequence segment pairs (HSSPs) significant at the $p = 0.01$ level. A *consistent matching array* is defined as a combination of HSSPs (optimizing overlaps) into a single "gapped" alignment. The significant segment pair alignment (SSPA) score for the sequence A and B is the maximal value with respect to all sets of consistently matching arrays, obtained by summing the segment scores. Normalization is then performed so that the SSPA score is

$$\sigma(A, B) = 100 \times \frac{\text{maximal total score w.r.t. consistent matching arrays}}{\max(\text{self score of } A, \text{self score of } B)} \qquad (3)$$

or, alternatively, normalization can be done with respect to the minimum of the two self-scores. This normalization allows comparison of proteins of different sizes and quality. In either case, $0 \leq \sigma(A,B) \leq 100$. For sequence pairs with at least one significant SSPA match, additional matching segments are identified at a lower probability threshold (typically $p = 0.50$) and appended to the alignment. The secondary lower threshold helps to fill in gaps between significant HSSPs. The SSPA method can be incorporated into a multiple alignment algorithm that employs dynamic programming to accommodate insertions/deletions and variable-length unaligned segments (Brocchieri and Karlin, 1998).

4. Analysis of marker arrays: *r*-scan analysis

A frequent problem in sequence analysis is to determine the statistical significance of *spacings* between specific markers distributed throughout a sequence. For example, one might seek to determine whether direct repeats or dyads (a sequence fragment followed by its reverse complement) are significantly clumped (many neighbors with short spacings) or over-dispersed. The method of *r-scans* provides a rigorous framework for such determinations (reviewed in Reinert *et al*., 2000). Let the r-scan length $R_i^{(r)}$ be the distance between marker i and marker $i + r$, that is the cumulative length of r distances between markers. Extremal statistics for the $\{R_i^{(r)}\}$ can be determined from their limiting distributions. The distribution of a marker is determined by comparing the distribution of $\{R_i^{(r)}\}$, calculated for a random sequence to those actually observed. Varying r permits detection of clustering or dispersion at different scales. Let the minimum and maximum r-scans be $m_r^* = \min_i R_i^{(r)}$ and $M_r^* = \max_i R_i^{(r)}$. The theoretical probabilities for a marker array of n points obey the asymptotic relations

$$\text{Prob}\left\{m_r^* \geq \frac{x}{n^{(1+1/r)}}\right\} \approx \exp\frac{-x^r}{r!} \text{ and}$$
$$\text{Prob}\left\{M_r^* \leq \frac{\ln n + (r-1)\ln(\ln n) + x}{n}\right\} \approx \exp\frac{-e^{-x}}{(r-1)!}. \qquad (4)$$

These equations provide thresholds for whether minimum and maximum observed spacings deviate significantly from random expectation. For example, setting the probability on the left-hand side to a required significance (typically 0.01) yields the formula $\exp(-x_b^r/r!) = 0.01$, which is solved for x_b, and the threshold value $b_r^* = x_b/n^{(1+1/r)}$ is then determined. For a sequence of length L, observed r-scan lengths of $m_r^* \leq b_r^* L$ define r-scan clusters. Similarly, significantly even spacing is indicated by $m_r^* > a_r^* L$, where a_r is determined from equations (4) by setting the probability to 0.99. Analogous expressions can be obtained for the maximal spacing M_r*, and markers are considered to be distributed randomly if the r-scan lengths are in the ranges $(a_r^* L,\ b_r^* L)$ and $(A_r^* L,\ B_r^* L)$. r-scan statistics can also identify whether counts in sliding window plots are significant. For a window of size w, let $N(t)$ be the number of markers in $(0,t)$. The critical value r^* that corresponds to a significance value p (e.g., $p = 0.01$) for the marker counts in the window can be calculated from

$$\text{Prob}\left\{\max_{w\leq t\leq 1}\,[N(t) - N(t-w)] > r\right\} = \text{Prob}\,\{m(r) \leq w\} \approx 1 - \exp\frac{-x^r}{r!} = p \qquad (5)$$

where $m(r)$ is the length of the minimum r-scan. Defining n by $x = wn^{1+1/r}$ gives $n(nw)^r/r! + \ln(1-p) = 0$, which can be solved numerically to give r^* for values of n, w, and p. This sliding window method correctly predicts the region of the lytic origin of replication for human cytomegalovirus (Masse *et al*., 1992).

5. Frequent words (oligonucleotides and peptides)

Another topic of interest is determination of sequence words that occur statistically more, or less, frequently than would be expected from random chance. For a sequence of length L, comprising letters drawn from an alphabet of size A, there is a natural word length s defined by the inequality $A^{s-1} \leq L < A^s$ and a natural copy number r determined by $(r-1)/r < (\log L)/\log A^s \leq r/(r+1)$. For sufficiently large L, the number of words of length s that occur more than r times is approximately Poisson distributed. This model, based on approximations to Poisson distributions concerned with generalized occupancy problems of balls-in-urns, works well in the case where the letter frequencies are roughly equal for the sequence (Karlin and Leung, 1991). In the case of a biased sequence, for example, an A + T rich genome such as *Haemophilus influenzae*, the method can be generalized to the case of words w that have separate frequencies p_w. The word size s is as defined previously, but the copy number threshold, r_w, for a particular word now satisfies $p_w L \exp(-p_w L)/r_w! \leq 1/L$. In this formalism, the lower the expected frequency of the word, the lower the cutoff for it to be considered frequent. If the inequality is saturated, at most, one frequent word is expected in a random sequence of the same length. For independent letters, $p_w = f_1 f_2 \ldots f_s$, where f_i is the frequency of occurrence of the ith letter in the sequence. For a Markov model, with transition probabilities $f_{i,j}$ between the ith and jth letters, $p_w = f_1 f_{1,2} \ldots f_{s-1,s}$. For the *H. influenzae* genome, $L \approx 1.8$ million bp, which, with $A = 4$ for a nucleotide alphabet, gives a natural frequent word length of $s = 9$ bp. Applying the copy number threshold reveals

that, amongst others, the sequence AAGTGCGGT and its inverted complement qualify as frequent words. These 9-mers can be recognized as the DNA-uptake signal sequences of *H. influenzae*, which are highly enriched in the genome of this bacterium and which facilitate the binding and uptake of *H. influenzae's* own DNA or DNA from closely related species. In *Escherichia coli*, REP elements and Chi sites qualify as frequent words, along with pentapeptides corresponding to the ATP-binding domain. For *Synechocystis*, the palindrome GGCGATCGCC is highly frequent and significantly evenly distributed. In eukaryotes, amino acid frequent words include words characteristic of zinc fingers (CGKAF, CEECG), chymotrypsin proteases (LTAAH, GDSGGP), serine/threonine and tyrosine kinases (ADFGL, FGQGT), and homeobox proteins (FQNRR, HFNRY).

6. Repeat structures

The patterns of significantly long repeats, frequency, length, and genomic environment may provide insights on evolution of genomes. All large repeats of the *H. influenzae* genome can be determined, allowing for error blocks (Leung *et al*., 1991). There are 150 occurrences in 51 repeat families; all involve at least 75% identities:

Sizes (bp)	25–29	30–39	40–59	60–99	100–139	140–179	180–399	400–699	700–1699	=3000
Occurrences	14	18	17	14	19	17	19	19	10	3

Spacings between repeats:

	tandem	2 bp–1 kb	1–10 kb	10–200 kb	=200 kb
Number of matches	18	8	7	28	33

Number of occurrences in distinct repeat families:

Family size	2	3	4	5	6	13	14
Count of families	38	5	3	2	1	1	1

Some atypical examples of direct repeats in *H. influenzae* include the following: (1) A ~3.2-kb direct repeat (97% identity). The first occurrence at about 1371–1380 kb in the published sequence contains two major insertions (0.9 and 4.2 kb long). The second uninterrupted occurrence is at 1416–1420 kb. (2) A 600-bp tandem-perfect direct repeat (one base insertion) spans the 3′ part of gene *guaB* and the 5′ part of gene *guaA*. (3) Three copies of ~500 bp with 97% identical sequences, all intergenic, around positions 173, 723, and 1344 kb.

Short Specialist Review

Errors in sequence assembly and corrections

Martti T. Tammi

National University of Singapore, Singapore

Björn Andersson

Karolinska Institutet, Stockholm, Sweden

1. Introduction

The major source of all the challenges is the limitation in sequencing technologies, which today allows us to routinely sequence only about 500 to 800 bases of contiguous DNA sequence. To overcome the limitation of short contiguous sequences, Frederick Sanger devised the shotgun sequencing technique and in 1982 demonstrated its potential by sequencing the genome of the bacteriophage lambda (Sanger *et al.*, 1982). The process of shotgun sequencing begins with physically shearing the original DNA molecules into small pieces as randomly as possible. The fragments are subsequently inserted into cloning vectors and amplified by growing them in *Escherichia coli*. The ends of the inserts are sequenced and sequenced reads assembled by specialized computer software, shotgun fragment assembly programs (Havlak *et al.*, 2004; Huang *et al.*, 2003; Huson *et al.*, 2001; Jaffe *et al.*, 2003; Kent and Haussler, 2001; Mullikin and Ning, 2003; Pevzner *et al.*, 2001; Pop *et al.*, 2004; Tammi *et al.*, 2003a; **www.phrap.org**.).

Despite continuous technology improvements during the three decades after Sanger devised the dideoxy DNA sequencing method (Sanger *et al.*, 1977), the average sequence length in routine production has only increased from about 200–300 contiguous bases to 500–800 bases. Although the average length has more than doubled, the increase is still too small to make a significant impact on the efficiency the fragment assembly. However, the throughput has increased enormously thanks to fluorescent detection of the base sequence (Smith *et al.*, 1986) and automatic sequencers.

Although the sequence assembly problem may appear simple, it is known to be NP-complete. In addition, sequence assembly is complicated by a number of

factors, but the three most important ones are sequencing or base-calling errors, genomic repeats, and polymorphism (*see* Article 11, **Algorithms for sequence errors**, Volume 7 and Article 2, **Algorithmic challenges in mammalian whole-genome assembly**, Volume 7).

2. Sequencing errors

Sequenced fragments contain base-calling errors, which can be incorrectly determined bases, insertions, and deletions. The number of errors tends to increase toward the ends of the reads. This is unfortunate, since most of the overlaps between reads are determined using the very ends of the sequenced fragments.

3. Repeats

In shotgun sequencing, the original idea of putting the puzzle of sequences together by using sequence similarity often fails in the case of repeats. Genomic sequence contains many kinds of repeats of varying lengths. Repeat copies may be identical or almost identical, only differing by a few bases. They can be dispersed all over the genome, and/or repeated in tandem, and contain any number of copies. Repeated regions are difficult to separate and cause assembly programs to assemble fragments originating from different copies together, resulting in erroneous assemblies. The combination of sequencing errors and repeated sequences pose the greatest challenge in shotgun fragment assembly. It is probably close to impossible to correctly assemble identical repeat copies. However, it may be argued that no information is lost, but identical repeat copies may cause large artificial genomic rearrangements. Repeats that are shorter than the average read length cause fewer problems than longer copies.

4. Polymorphism

In whole-genome shogun sequencing, polymorphism complicates the assembly of nearly identical repeats and in some cases also nonrepetitive regions, but it is not a problem in a “clone-by-clone” approach, since only one variant of each genomic region is sampled (*see* Article 12, **Polymorphism and sequence assembly**, Volume 7).

5. Incomplete coverage

The fraction $\frac{NL}{G}$ represents the amount of oversampling of the genomic sequence G, where N is the number of sampled reads and L is the average length of the reads. This is also called *coverage*. Some assembly programs use statistical methods, searching the best overlaps and may easily assign false overlaps if no better overlap is present due to lack of coverage. There are genomic regions that are impossible to sequence due to biological reasons. However, the output from an assembly program

may consist of several contigs also due to an erroneous assembly, or due to the nature of sampling process itself, all resulting in gaps in coverage. The coverage has a certain probability to be zero, depending on the amount of sampling. When reads are sequenced from random fragments, not all genomics positions are equally sampled. The Lander and Waterman expression (Lander and Waterman, 1988) can be used to calculate the average number of gaps, contigs, and their average length in a shotgun project; if a target sequence G is redundantly sampled, at an average coverage $\overline{c}$ and assuming that the sheared fragments are uniformly distributed along the genomic sequence, the coverage at a give base b is a Poisson random variable with mean $\overline{c}$:

$$P(\text{base } b \text{ convered by } k \text{ fragments}) = \frac{e^{-\overline{c}} \cdot \overline{c}^k}{k!} \tag{1}$$

For example, the fraction of G that is covered by at least one fragment is $1 - e^{-\overline{c}}$. The Lander and Waterman expressions can also be used to compute the fraction of reads involved in overlaps, detected by an assembly program, but which ones of the particular gaps are due to an erroneous assembly of reads is of course hard to estimate. However, some methods have used a high coverage as an indicator of many copies of repeats assembled together (Myers *et al*., 2000).

An additional complicating factor is the unknown orientation of the shotgun fragments. It is not known from which DNA strand each sequenced fragment originates, and this increases the complexity of the assembly task. Hence, a read may be present on one strand or it is the reverse complement sequence on the other strand. In a sequencing project containing one million sequenced reads, a complementary set of reads must be generated resulting in two million reads. The complete set is required for the evaluation of all overlaps. This and possible contamination and unremoved vector sequences may cause severe errors in assemblies.

A number of methods have been invented in order to address these problems. One powerful way is the assignment of error probabilities to base-calls (Ewing and Green, 1998). The knowledge of the quality of the base-calls allows efficient trimming of the reads and statistical evaluation of candidate overlaps (**www.phrap.org**). A detailed analysis of highly similar repeat copies may be performed (Tammi *et al*., 2002) as well as error correction of the sequenced reads (Tammi *et al*., 2003b; Pevzner *et al*., 2001). Since clone inserts are usually sequenced from both ends and the insert lengths are known, this information can be used to position the read pairs within the assembly (Edwards and Caskey, 1990; Myers *et al*., 2000). It is likely that the combination of the information given by sequenced pairs and statistical methods for analysis of highly similar repeats yields the most powerful approach in the struggle against misassemblies caused by repeats and sequencing errors. It is, however, clear that current sequence assembly software is only capable of producing a draft sequence, and much labor-intensive manual finishing is required to arrive at a good quality, reliable, finished sequence.

The human genome was sequenced both by a public (Lander *et al*., 2001) and a private initiative (Venter *et al*., 2001). The public initiative used the hierarchical or "clone-by-clone" approach, a method that involves extensive mapping. The

mapping step was avoided by the whole-genome shotgun (WGS) approach, which was used by Celera in the privately funded effort. A comparison of these approaches by She *et al*. (2004) showed that the WGS approach runs into problems on the repeated parts of the genome. Apart from the highly repetitive telomere and centromere regions that are not targeted by either initiative, the WGS approach was unable to adequately resolve larger than 15 kb where the difference between copies was 3% or less. About 4% of the sequence was lost or erroneously assembled because of collapsed repeated regions. This leads to significant reduction of the actual genome length and the loss of many biologically important regions including genes. It is likely that a combination of the sequencing strategies is the most advantageous one.

Basic Techniques and Approaches

Genome maps and their use in sequence assembly

Paul H. Dear
MRC Laboratory of Molecular Biology, Cambridge, UK

1. Introduction

Genomes range in size from around a million base pairs to many thousands of millions, and yet a typical sequencing reaction yields less than a thousand base pairs of contiguous sequence information. From these tiny fragments of data, the complete genome sequence must be reconstructed as accurately and as completely as possible if genes and other features are to be reliably identified. For the smallest and simplest genomes, the so-called "shotgun" approach is sometimes sufficient: the genome is fragmented and subcloned, and many randomly selected clones are sequenced. As the data accumulates, overlapping stretches of sequence are identified computationally to build contiguous sequences ("contigs") that grow and merge as the shotgun sequencing project progresses. When enough sequence data has been obtained, the hope is that a single contig can be assembled representing each chromosome.

For more complex genomes, however, shotgun sequencing alone is insufficient. Some parts of the genome may prove refractory to cloning, leaving gaps between a large number of unlinked (and therefore unordered) contigs. Other parts may contain complex repeats – large tracts of sequence that occur at multiple points in the genome – making unambiguous assembly impossible.

Genome maps address this problem by defining the relative positions of selected sequence features over distances of a few kilobases or more, complementing the short-range information provided by the shotgun data. They thus act like the index of a book, which gives the locations of keywords to help the reader navigate the detailed text. This article will outline the principal methods of genome mapping and will then consider how these approaches are integrated into the sequencing process to produce finished genome sequences.

2. Methods of genome mapping

A number of methods have evolved to produce maps of genomes, but here we will focus only on those methods that give sufficient detail to assist the assembly of sequence data. This largely excludes genetic mapping and fluorescence in situ

hybridization, both of which yield coarse maps that are useful mainly for validating the final sequence assembly on the largest scale.

2.1. Physical mapping

Physical (or clone-based) mapping is conceptually similar to shotgun sequence assembly but takes place on a much larger scale (*see* Article 13, **YAC-STS content mapping**, Volume 3 and Article 18, **Fingerprint mapping**, Volume 3). The aim is to find a series (or "tiling path") of cloned fragments that represent consecutive overlapping segments of the genome, but the clones that are used are one or two orders of magnitude larger than the small-insert clones used for shotgun sequencing. Typically, the genome is first cloned in BACs (bacterial artificial chromosomes), with insert sizes of 50–200 kb, and each clone in the library is analyzed. This analysis may involve tabulating the sizes of restriction fragments produced when each clone is digested with a chosen restriction enzyme ("fingerprinting") or testing each of the clones by PCR for the presence of many different specific sequences (known as "sequence tagged sites" or STSs, perhaps chosen from the early data from a shotgun sequencing project). Two clones are then inferred to overlap if they are found to have several restriction-fragment sizes in common or if they both contain the same STS (Figure 1).

Physical mapping suffers from the same limitations as the finer-scale shotgun sequence assembly: regions of the genome that cannot be cloned in BACs leave gaps in the physical map, while very large repetitive tracts (larger than the size of a single BAC clone) can lead to ambiguities in the construction of the tiling path. These problems can be partly overcome in some cases by the use of yeast artificial chromosomes (YACs) as the cloning vector, as these will accept larger inserts and will propagate some sequences that are unstable in bacterial cloning systems. However, YACs are technically more difficult to work with and are also more susceptible to a range of cloning artifacts. In spite of these difficulties, physical mapping is widely used in genome sequencing, often in conjunction with other approaches.

2.2. Optical mapping

Optical mapping (Samad *et al*., 1995; Zhou *et al*., 2003) is an elegant method, though it has so far been applied only to a rather narrow range of genomes. Genomic DNA is spread across a glass slide in such a way that the long molecules are stretched out in one direction and are loosely bound to the surface. The DNA is stained with a fluorescent dye and then treated with a restriction enzyme that cleaves the DNA at each occurrence of the enzyme's recognition sequence. When examined through a fluorescence microscope, the long DNA molecules appear as dotted lines, broken at each restriction site, and the sizes of the restriction fragments can be measured directly. By compiling many such images, a fairly precise "restriction map" is generated, showing the location of all the restriction sites in the genome. The pattern of restriction sites in the contigs produced by a

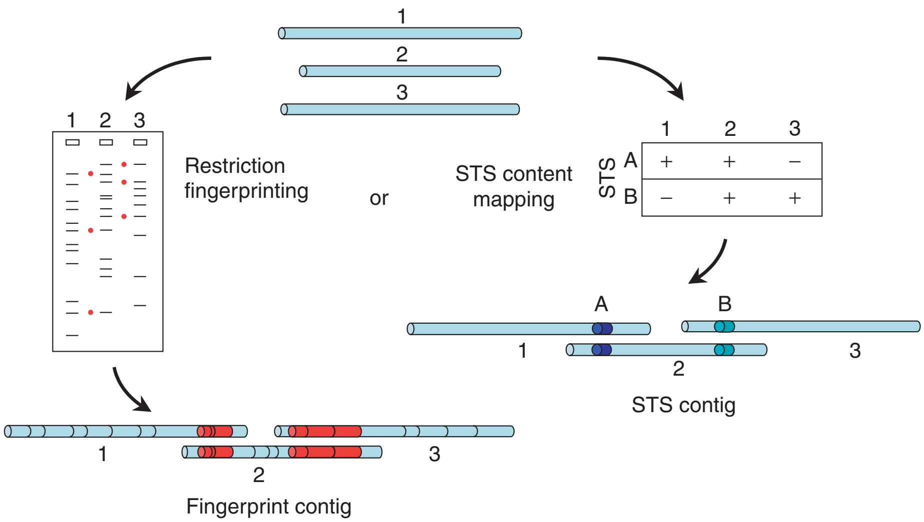

Figure 1 Physical mapping. Large-insert clones (top) can be characterized by digesting them with a restriction enzyme and measuring the sizes of the resulting fragments on a gel (left). Clones that have several fragment sizes in common (indicated by red dots) can be assumed to overlap, with the shared fragments arising from the regions of overlap (bottom left; common restriction fragments shown in red). Alternatively (right), each clone can be tested for the presence of many different STS markers (in this case, two markers A and B). Clones that carry the same STS markers can be inferred to overlap, the shared markers lying in the region of overlap (bottom; markers indicated by colored segments)

shotgun sequencing project can then be compared with the genome-wide restriction map to find the precise location of each contig in the genome (Figure 2).

The biggest advantage of optical mapping is its independence from cloning and the associated artifacts, though the data it produces (locations of restriction sites) is not as rich as that produced by other methods, complicating its direct use in large genomes.

2.3. *Radiation hybrid mapping*

Radiation hybrid (RH) mapping is conceptually similar to genetic linkage mapping (*see* Article 15, **Linkage mapping**, Volume 3) and gives information on the order and spacing of selected sequences (STSs) in the genome (Cox *et al*., 1990; *see also* Article 14, **The construction and use of radiation hybrid maps in genomic research**, Volume 3). Living cells of the species to be mapped (the "donor") are irradiated to break their chromosomes at random locations and are then fused with unirradiated cells of another species (the "host"). The result is a population of hybrid cells, each containing the host chromosomes along with a few random fragments of the donor genome. A library of many such cells is then tested, by PCR, to determine which donor-derived STSs are present in each hybrid. If two STSs are close to one another in the donor genome, then they will often remain on the same chromosome fragment after irradiation and hence will often be found together (or

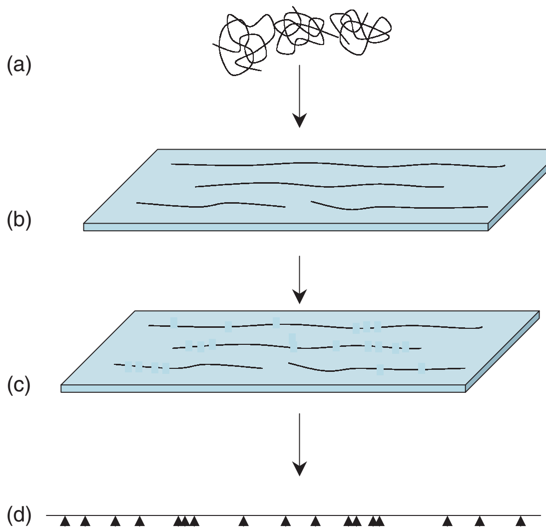

Figure 2 Optical mapping. Large fragments of genomic DNA (a) are spread and aligned on a glass surface (b) and stained for visualization. A restriction enzyme cuts the molecules at its recognition sites, and the cuts can be seen using a fluorescence microscope (c). Computerized measurement and analysis of many such images covering overlapping parts of the genome allows the precise pattern (d) of restriction sites (indicated by arrowheads) in the genome to be determined

"cosegregate") in the same hybrid cell. Conversely, STSs lying far apart in the donor genome will reside on different fragments after the irradiation and hence will segregate independently amongst the hybrids. By analyzing cosegregation frequencies, therefore, distances between STS markers can be estimated and a map constructed. The basic principle is similar to that used in HAPPY mapping (see below), as illustrated in Figure 3.

RH mapping is a powerful tool used to making maps of large genomes since it can be used to map widely spaced markers. However, it suffers from some technical limitations, including the difficulty of making hybrid cells from many donor species, the complicating presence of the host genome in the hybrids, and artifacts caused by biological factors influencing the retention of donor fragments in the hybrid cells.

2.4. *HAPPY mapping*

HAPPY mapping (Dear and Cook, 1993; *see also* Article 22, **The Happy mapping approach**, Volume 3) is analogous to RH mapping, but is entirely an in vitro process (Figure 3). Again, it begins by randomly breaking genomic DNA of the species to be mapped, either by mechanical means or by radiation. However, instead of segregating the fragments into hybrid cells, they are segregated simply by diluting and dispensing them into a series of samples, each containing only a few random fragments of the genome. Each sample is then screened by PCR to determine

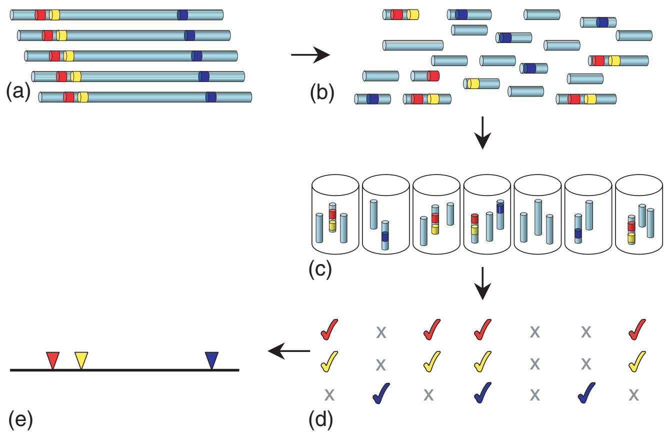

Figure 3 HAPPY mapping. Genomic DNA (a; colored segments represent STS markers) is broken into random fragments (b), which are greatly diluted and dispensed into a series of samples (c). Each sample is tested by PCR to determine the markers it contains (d). Closely linked markers (red and yellow) will tend to occur together (cosegregate) amongst the samples. By analyzing the cosegregation of many such markers, their order and spacing along the chromosome can be calculated to produce a map (e). The process of radiation hybrid mapping is similar, except that the DNA fragments are propagated in hybrid cells rather than as in vitro samples

the specific sequences (STSs) it contains. Much as in RH mapping, cosegregation frequencies can be used to deduce the order and spacing of the markers.

The main limitation of HAPPY mapping is the technical challenge of preparing and analyzing minuscule DNA samples, although this is now relatively straightforward. Its advantages arise from its in vitro nature and the consequent control that this gives. The method works equally well on all genomes and does not suffer from biological artifacts induced by specific sequences. Moreover, by choosing how finely to break the DNA at the outset, the level of detail in the maps can be precisely controlled, from relatively coarse long-range maps suited to large genomes (Dear *et al*., 1998) to detailed maps with accuracies of a few kilobases (Bankier *et al*., 2003).

3. Mapping as part of a sequencing program

Very few genome sequencing programs use a single methodology in its pure form, but we can outline the elements of two very different, simplified strategies as examples.

In the “top-down” approach, a physical map consisting of overlapping large-insert clones (typically BACs) is first constructed and carefully checked. Some years ago, physical mapping was conducted exclusively using the fingerprinting approach. Nowadays, it is often done by STS content mapping, and, in many cases, a proportion of the STSs would have been previously mapped by RH or other methods to provide an additional layer of positional information and to guard against errors in the physical map. Once the physical map is complete, a set of

mapped clones is chosen that covers the genome with the minimum of overlap. Each of the BAC clones in this "minimal tiling path" is then purified, subcloned as small fragments, and sequenced as an individual shotgun project. The genome is therefore sequenced segment by segment in an orderly manner.

The "bottom-up" approach, conversely, starts with extensive whole-genome shotgun sequencing and assembling of the data into sequence contigs. The contigs typically grow and merge as more data are accumulated, until a point of diminishing returns is reached where new sequence data largely duplicates those that are already obtained. At this point, the genome consists of many contigs, separated either by difficult-to-clone regions or by repeats that impede further unambiguous assembly. Mapping strategies are then used to find the arrangement of these contigs in the genome. For example, short sequences chosen from one end of each contig can be HAPPY mapped, showing how the sequence contigs are arranged in the genome. This is often sufficient to resolve repeat-induced gaps; clone-gaps can be closed, for example, by PCR between the sequences now known to flank the gap.

In reality, however, most genome projects use a mixed strategy to bring the sequence to completion. For example, the publicly funded human genome project began as a "top-down" approach, starting with detailed BAC physical maps, reinforced by RH and other marker-based maps. In response to a commercially funded pure shotgun approach, it then adopted a more shotgun-dependent strategy to allow rapid production of an unfinished draft sequence. The public consortium has since largely finished the sequence through a return to more methodical map-led approaches, whereas the pure shotgun strategy of Celera left the genome in over 100 000 unlinked contigs, as expected for a sequence of this size and complexity.

Most large-genome sequencing projects now rely heavily on a combination of shotgun sequencing and physical mapping approaches and also on "map as you go" strategies in which initial sequence data is used to identify those BAC clones that overlap with the existing contigs and those that can be sequenced to extend the contigs in a stepwise manner.

Conversely, the sequencing of the genome of the amoeba *Dictyostelium discoideum* began as a modified bottom-up approach, with shotgun sequencing not of the whole genome but of individual purified chromosomes. HAPPY mapping was then used to locate each sequence contig precisely in the genome, allowing the gaps in the sequence to be closed methodically using a variety of approaches. This type of approach is widely favored for smaller genomes since the initial shotgun phase yields valuable sequence data, and the subsequent mapping (by whichever means) can be directed toward closing the remaining gaps.

Basic Techniques and Approaches

Repeatfinding

Richard Sucgang
Baylor College of Medicine, Houston, TX, USA

Genomes in general, and eukaryotic genomes in particular, are rife with segments of repetitive sequence. Repetition is the most obvious pattern found in genetic information, and is usually indicative of a biologically significant motif or landmark in that particular biomolecule. Repetitive segments of DNA appear to be necessary for the structural function of centromeres and telomeres (Louis, 2002; Schueler *et al*., 2001). Gene duplications also lead to repetitive motifs, such as those found in biologically important regions such as ribosomal RNA genes (Heilig *et al*., 2003) or the human Y chromosome (Repping *et al*., 2002), reflecting the evolutionary importance of these areas. Consequently, some of the earliest analytical tools developed involve detection, identification, and classification of repeat regions in protein and DNA sequences. With the availability of whole genomes, such repeat finding algorithms are an essential aspect of genome level analysis and annotation. In fact, repetitive regions often confound the assembly stage of genome sequencing, so the successful assembly of whole genomes is itself dependent on identifying and masking repeats.

Although identifying repeats in biological sequences would, on its face, appear to be a mathematically simple problem of searching for repeated substrings within a larger string, several factors confound the issue. Biological repeat segments are not necessarily exact repeats, and the periodicity of the pattern seldom matches an exact formula. Despite these fuzzy boundaries, biological repeats retain a physiological significance, and therefore, the algorithms written have accommodated these inexact specifications. In addition, comparisons of repeat motifs within and among whole genomes demand logarithmically increasing amounts of memory and processing power; most recent implementations of repeat finding software utilize more sophisticated searching algorithms such as suffix-tree mapping to address these issues (Delcher *et al*., 1999).

In general, repeat analysis software packages have focused on one or more of the following tasks: detection of repeat patterns (which can be subtle), de novo identification of basic repeat units (Bao and Eddy, 2002), clustering and classification of known repeat units (Volfovsky *et al*., 2001), and curation of such repeats. In this section, we will take a survey of the different software implementations for repeat finding.

Detection of repeated segments in strings of characters is a difficult problem in computation, particularly in biology where the basic unit of repetition can vary not

only in sequence but also in size and displacement. The human eye, however, is adept at picking out patterns laid out in a two-dimensional figure; thus, one of the simplest and yet most effective means of detecting repeated patterns in sequences is the dot-matrix plot (Gibbs and McIntyre, 1970). At the simplest implementation of this plot, two sequences that are being compared are laid out along the two axes of a two-dimensional grid. For every character in common between the two strings, one dot is placed at the intersection of the two coordinates. While this approach can be used to visualize the commonalities between any two strings, when the same string is laid on both axes, repeated motifs become evident to the human eye (Figure 1). A central diagonal is always present as the sequence is compared against itself, direct repeats manifest as parallel lines to the central diagonal, and inverted repeats are present as perpendicular lines. The distance from the diagonal indicates displacement, and palindromic repeats cross the central diagonal. This approach has proved to be so effective in detecting repeat motifs that despite increasing sophistication in implementation, the basic algorithm has remained essentially unchanged.

The earliest implementation as a software package was described by Pustell and Kafatos (1982), and implementations are found in various software packages ranging from commercial to open source; one such example is dottup, a component of the EMBOSS package (Rice *et al*., 2000). Since a dot-matrix plot relies on the pattern recognition skills of the human eye, good interactivity and flexibility

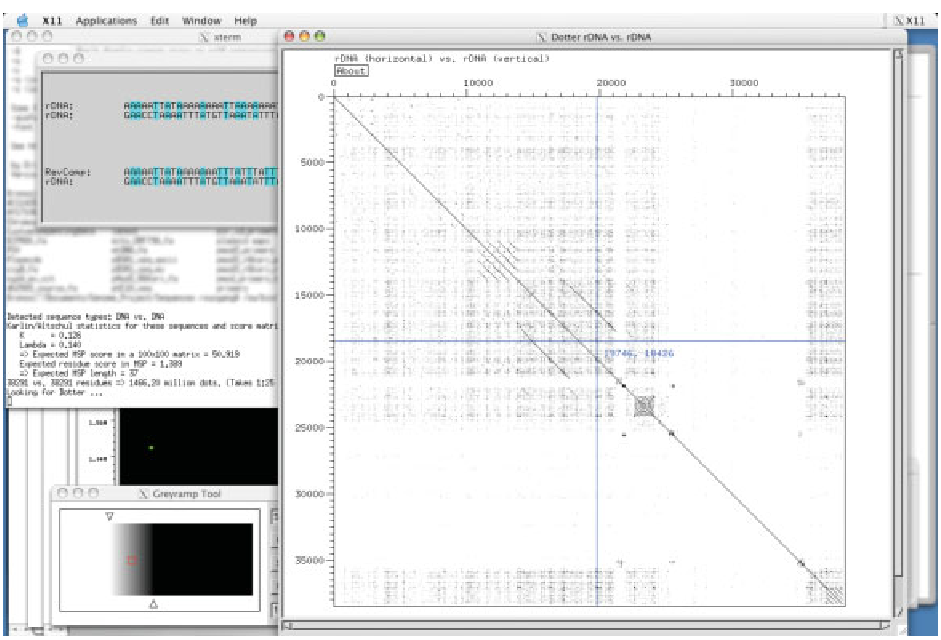

Figure 1 The dotter interface. Loaded here is one arm of the *Dictyostelium discoideum* extrachromosomal rDNA element, lines parallel to the central diagonal indicate direct repeats in the sequence. Clusters of shorter repeats are seen as multiple parallel lines. Note the greyramp tool at the lower left corner that can be used to set the threshold of the image to improve detection of shorter repeat motifs

with the manipulation of the dot-matrix image is key to a good implementation. While lines can denote significant repeat structures, nonspecific or low complexity matches will be displayed as clouds of dots that can occlude the visibility of significant sequence features. Perhaps the most sophisticated interface for exploring dot-matrix plots currently available is in the dotter package (Sonnhammer and Durbin, 1995). Relying on the X11 graphical user layer in Unix, the dotter package plots the images as a gray-scale plot, and provides a gray ramping tool that permits on the fly alterations to the visualization threshold. Dynamic zooming into segments, and the ability to export to high-resolution PostScript data completes the package.

While dotter theoretically presents no real limit to the amount of data that it can process, realistically, as the input data increases (such as that of a chromosome-sized piece of DNA), the dotter package slows down dramatically. Much of the performance bottleneck is in the matching algorithm used to align segments to the genome. Word-search-based algorithms that rely on preindexing a table of all possible word combinations in a sequence are far faster in traversing large sequences, and is the method implemented by the software package lbdot (Huang and Zhang, 2004). Although the interface is less polished for exploring the resulting plot, it is able to process large sequences at a fraction of the time and memory required by dotter.

Inherent to the problem of detecting repeats is the need to align and search whole genomes efficiently. The REPuter package efficiently searches for repeats and palindromes in genome scale sequences. Initially implemented just to detect the largest exact matches for the substrings, it has since been improved to permit the presence of degenerate repeats with allowable mismatches (Kurtz *et al*., 2001). It is available in limited form for Web-based interaction, but a licensed stand-alone version provides increased flexibility. An approach to aligning whole genomes that uses the suffix-tree algorithm to detect repeats is the MUMmer package from The Institute of Genome Research (TIGR) (Kurtz *et al*., 2004). Now at version 3, the MUMmer package is uniquely flexible in not only aligning any genome (or fragment thereof) with any other, but can base the alignment on the protein coding potential of the genome, detecting duplicated genes that may have diverged sufficiently on the nucleotide level to avoid detection with a direct dot-matrix plot (Figure 2). The MUMmer package is fast enough that an on-line version is available for arbitrary alignments between the different completed microbial genomes archived at the Comprehensive Microbial Resource at TIGR (Peterson *et al*., 2001). More recently, a new Repeat Analysis Program has become available that improves on these approaches by indexing gapped words, increasing the sensitivity of the word-searching method (Campagna *et al*., 2005).

Eukaryotic genomes carry not only a load of simple and tandem repeats but also a number of interspersed repeats, particularly those deriving from transposable elements and their by-products. Although simple repeats are easy to identify, repeated de novo identification of more complex repeats through word-finding can be impractical for every new genome that needs to be analyzed, or at the very least inefficient for genomes that are closely related to a previously analyzed one. In these circumstances, repeat finding can be accelerated by the use of a preexisting library of curated known repeat sequences.

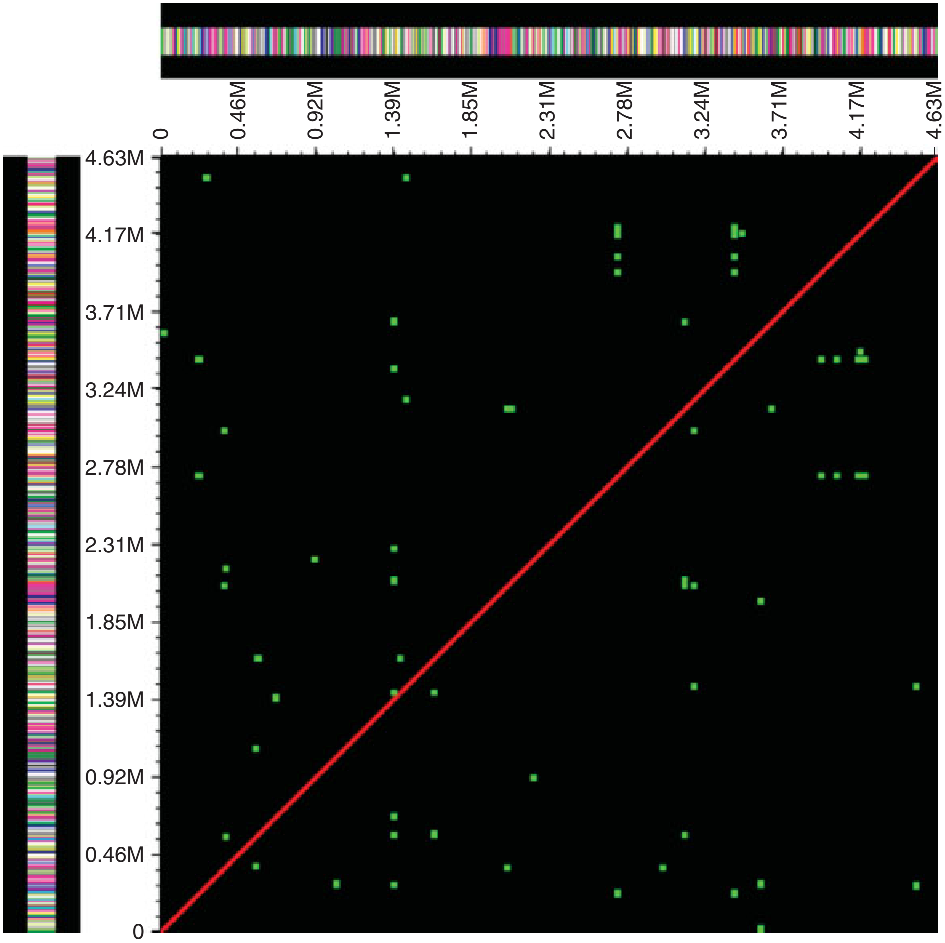

Figure 2 MUMmer output. This illustrates MUMmer displaying the *E. coli* genome against itself, highlighting the presence of short inverted repeats. For this display, the minimum sensitivity is 100 bp. A red dot indicates an alignment in the same direction, and a green dot for the opposite direction. The multicolored bars on each side show the gene density for the chromosome, each colored bar representing one gene

Although repeated sequence motifs can be indicative of biologically important regions of genomes, the sheer abundance of interspersed complex repetitive sequences can obscure annotation and analysis efforts, particularly if a particular element encodes potential coding sequences that can interfere with ab initio gene prediction software. Thus, masking out the repeats is an equally important subsequent step to repeat detection. The most common software package for this purpose is RepeatMasker, now an open source package housed by the Institute for Systems Biology (Smit *et al*., 1996–2004). At its core, RepeatMasker relies on a database of known repeat sequences, and the matching algorithm cross_match (Gordon *et al*., 1998). However, at the highest sensitivity settings, cross_match can be very slow with large sequences, leading to the development of

the accelerator package MaskerAid (Bedell *et al*., 2000), which replaced the matching algorithm with the significantly faster WU-BLAST algorithm. The current implementation of RepeatMasker integrates the option to use the WU-BLAST method.

Databases of prototypic sequences from repetitive elements are key to the operation of such masking software. Although the on-line resource RepBase was originally crafted to curate prototypic sequences from the human genome, it has since expanded to accommodate most known eukaryotic repeats, and releases them in database form for use by programs such as RepeatMasker (Jurka *et al*., 1992). Managed by the nonprofit Genetic Information Research Institute, RepBase also electronically publishes a specialized electronic journal dedicated to studying eukaryotic repeats called RepBase Reports. The RepBase team also implements an alternative masking program called CENSOR (Jurka *et al*., 1996). Housed in Taiwan, the Repeat Sequence Database is another such database, originally designed to explore the relationship between repetitive sequence data and transcriptional activation sites (Horng *et al*., 2003).

As with most software implementations, the packages described in this section continue to evolve, and will no doubt be supplemented and supplanted by new software in the future. Table 1 summarizes the different URLs where the software is available, and all are either open source or available for free for academic use at the time of this writing.

Basic Techniques and Approaches

Graphs and metrics

Andreas Dress
Max-Planck-Institut für Mathematik in den Naturwissenschaften, Inselstrasse, Leipzig, Germany

1. Generalities

Graphs and metrics are structures that allow to specify and represent mutual relationship between pairs of objects from a given collection of objects under consideration. The most abstract form of representation consists in just a list specifying all pairs of objects that are considered to be "related" (relative to some preconceived concept of relatedness). Additional information regarding a "quantifiable degree of relatedness" can be specified by providing, in general for every pair x, y of objects, a nonnegative real number $S(x, y)$ measuring their *similarity* – or, conversely, a number $D(x, y)$ measuring their *dissimilarity* (or *distance*).

2. Basic definitions

1. In consequence, one defines a (simple undirected) *graph* G to be a pair (V, E) consisting of a set $V = V_G$ called the *vertex set* of G (representing the objects) and a subset $E = E_G$ of the set $\binom{V}{2}$ of 2-subsets of V called its *edge set*. The *degree* $d_G(v)$ of a vertex $v \in V$ is the number of elements in its *G-neighborhood* $N_G(v) := \{u \in V : \{v, u\} \in E\}$. If V is a finite set of cardinality $|V| =: n = n(G)$ – in which case G is called a finite graph – one has $0 \leq d_G(v) < n$ for every $v \in V$, $2|E| = \sum_{v \in V} d_G(v) = \sum_{i=0}^{n-1} i\, n_i$ with $n_i = n_i(G) := |V_i(G)|$, the cardinality of the set $V_i(G) := \{v \in V : d_G(v) = i\}$ of vertices of degree i, and $|V| = \sum_i n_i$ (which, by the way, implies that every finite graph contains at least two vertices of the same degree because $n_i \leq 1$ for all $i = 0, 1, \ldots, n-1$ would imply $n_i = 1$ for all $i = 0, 1, \ldots, n-1$, while $n_i = 0$ holds for all $i > n - (n_0 + 1)$). A *clique* of G is a subset C of V with $\binom{C}{2} \subseteq E$, an *independent* set of G is a subset I of V with $\binom{I}{2} \cap E = \emptyset$, a *G-path* of *length* ℓ from a vertex v to a vertex u is a sequence $v_0, v_1, \ldots, v_\ell$ of $\ell + 1$ vertices on V with $v_0 = v, v_\ell = u$, and $\{v_0, v_1\}, \{v_1, v_2\}, \ldots, \{v_{\ell-1}, v_\ell\} \in E$. A *connected component* of G is a minimal nonempty subset C of V such that $u \in C$ holds for every $u \in V$ for which a G-path from u to some vertex $v \in C$ exists (or, equivalently, a maximal subset C of V such that a G-path from u to v exists for any two vertices $u, v \in G$). The vertex sets of the connected components of G form a *partition* of V, denoted

by π_G. G is connected if $|\pi_G| = 1$ (or, equivalently, $\pi_G = \{V\}$) holds. A *G-cycle* is a path $x_0, x_1, \ldots, x_n$ with $x_n = x_0$ and $|\{x_1, \ldots, x_n\}| = n > 2$. G is called a *tree* if it is connected and does not contain any G-cycle. One has $|V| \leq |E| + 1$ for any finite connected graph $G = (V, E)$, with equality holding iff (=if and only if) G is a tree, implying that $2\sum_{i>0} n_i = 2|V| = 2 + 2|E| = 2 + \sum_{i>0} i\, n_i$ and, therefore, $n_1 = 2 + \sum_{i>2}(i-2)n_i > 1$ and $2 + \sum_{i>1}(i-1)n_i = |V|$ hold for every finite tree with at least two vertices. More generally, the *cycle number* $C_1(G); := |E| + |\pi_G| - |V|$ is a non-negative integer for every finite graph G. For every connected graph $G = (V, E)$, there exists a *spanning tree*, that is, a tree with vertex set V whose edge set is a subset of E. Every finite tree (V, E) with $|V| \geq 2$ contains at least two *leaves*, that is, vertices of degree 1, and – in case $|V| \geq 5$ and $n_2 = O$ – at least two disjoint *cherries*, that is, pairs of distinct leaves u, v with $N_G(u) = N_G(v)$.

2. Given any set X, a map D from $X \times X := \{(x, y): x, y \in X\}$ into the set $\mathbb{R} \cup \{+\infty\}$ is called *symmetric* if $D(x, y) = D(y, x)$, a *similarity* if $D(x, x) \geq D(x, y)$, and a *dissimilarity* if $D(x, x) = 0 \leq D(x, y)$ holds for all $x, y \in X$. A dissimilarity is called a *metric* if $D(x, y) \leq D(x, z) + D(y, z)$ holds for all $x, y, z \in X$. The *diameter* $D(C)$ of a subset C of X relative to a dissimilarity D is defined by $D(C) := \sup(D(x, y) : x, y \in C)$. The D-rank $\mathrm{rk}_x^D(y)$ of an element $y \in X$ relative to some element $x \in X$ is defined by $\mathrm{rk}_x^D(y) := |\{z \in X : D(x, z) \leq D(x, y)\}|$ and the *D-rank* of a subset C of X by $\mathrm{rk}^D(C) := \max(\mathrm{rk}_x^D(y) : x, y \in C)$. One has $\mathrm{exc}^D(C) := \mathrm{rk}^D(C) - |C| \geq 0$ for every $C \subseteq X$, and $|C_1 \cup C_2| \leq \max\left(\mathrm{rk}^D(C_1), \mathrm{rk}^D(C_2)\right) \leq \max(|C_1|, |C_2|) + \max(\mathrm{exc}^D(C_1), \mathrm{exc}^D(C_2))$ for all $C_1, C_2 \subseteq X$ with $C_1 \cap C_2 \neq \emptyset$. In particular, one has $C_1 \cap C_2 = \emptyset$, $C_1 \subseteq C_2$, or $C_2 \subseteq C_1$ for all $C_1, C_2 \subseteq X$ with $\mathrm{exc}^D(C_1) = \mathrm{exc}^D(C_2) = 0$. Note that $\mathrm{rk}_x^{D_1}(y) = \mathrm{rk}_x^{D_2}(y)$ holds for all $x, y \in X$ for any two *homologous* dissimilarities D_1 and D_2, that is, with $D_1(x, z) \leq D_1(x, y) \Leftrightarrow D_2(x, z) \leq D(x, y)$ for all x, y, z in X.

Given n sets $X_1, \ldots, X_n$ with metrics $D_i : X_i \times X_i \to \mathbb{R}_{\geq 0}$ $(i = 1, \ldots, n)$, the product space $X_1 \times \cdots \times X_n$ consisting of all sequences $(x_1, \ldots, x_n)$ with $x_i \in X_i$ for all $i = 1 \ldots, n$, is a metric space relative to the metric $D := D_1 \times \cdots \times D_n$ defined by $D((x_1, \ldots, x_n), (x\prime_1, \ldots, x\prime_n)) := \sum_{i=1}^{n} D_i(x_i, x\prime_i)$ for any two sequences $(x_1, \ldots, x_n)$, $(x'_1, \ldots, x'_n)$ in $X_1 \times \cdots \times X_n$.

3. From graphs to metrics

Given a graph $G = (V, E)$ together with a *weighting scheme* $w : E \to \mathbb{R}_{>0}$, there exists a unique largest metric $D = D_{(G,w)} : V \times V \to \mathbb{R}_{\geq 0} U\{\infty\}$ with $D(u, v) \leq w(\{u, v\}$ for all $u, v \in V$ with $\{u, v\} \in E$. In case $w(e) = 1$ holds for all $e \in E$, one also writes D_G instead of $D_{(G,w)}$. Clearly, one has (1) $D_{(G,w)}(x, y) = +\infty$ for some $x, y \in V$ (and every weighting scheme w) iff no G-path from x to y exists, (2) the diameter $D_G(C)$ of a subset C of V equals 1 iff C is a clique, (3) $\{u, v\} \in E$ for any two elements $u, v \in V$ iff $D_G(u, v) = 1$ holds and, provided G is finite, also (4) $D_{(G,w)}(x, y) + D_{(G,w)}(u, v) \leq \max(D_{(G,w)}(x, u) + D_{(G,w)}(y, v), D_{(G,w)}(x, v) + D_{(G,w)}(y, u))$ for all $x, y, u, v \in V$ for some (or all) weighting scheme(s) w iff G is

a tree in which case a map $f : V_1 \to \mathbb{R}$ is of the form $f = f_v : V_1 \to \mathbb{R} : x \mapsto D_{(G,w)}(x, v)$ for some vertex $v \in V$ of degree $k \geq 3$ iff $f(x) = \max(D_{(G,w)}(x, y) - f(y){:}y \in V_1)$ holds for all $x \in V_1$ and a clique of cardinality k exists in the graph $G_f{:=}(V_1, E_F)$ with $E_f := \{\{x, y\} \in \binom{V_1}{2} : f(x) + f(y) = D_{(G,w)}(x, y)\}$; so, we can recover V (and then also E and w) from the restriction of $D_{(G,w)}$ to V_1 in case $n_2 = 0$ holds.

4. From metrics to graphs

Given a dissimilarity $D : X \times X :\to \mathbb{R}_{\geq 0}$ defined on a finite set X and a number $r \in \mathbb{R}$, put $E(r) := E_D(r) := \{\{x, y\} \in \binom{X}{2} : D(x, y) \leq r\}$ and $G(r) = G_D(r){:=} (X, E(r))$. As $r_1 \leq r_2$ implies $E(r_1){\subseteq}E(r_2)$, every connected component of $G(r_2)$ is a disjoint union of connected components of $G(r_1)$ in this case, implying that the graph $\mathcal{C}(\mathcal{D})$ with vertex set $C(D) := \bigcup_{r\geq 0} \pi_{G(r)}$ and edge set all subsets $\{U_1, U_2\}$ of $C(D)$ with $|\{U \in C(D){:}U_1 \subsetneq U \subseteq U_2\}| = 2$ is a tree. Similarly, the graph $\mathcal{R}(\mathcal{D})$ with vertex set $A(D){:=}\{C{\subseteq}X{:}\mathrm{exc}^D(C) = 0\}$ and edge set all subsets $\{C_1, C_2\}$ of $A(D)$ with $|\{C \in A(D){:}C_1 \subsetneq C \subseteq C_2\}| = 2$ is also a tree. If X is a set of species and D a measure of their "genetic dissimilarity", these trees can be viewed as putative phylogenetic trees for X.

Of interest is also the graph with vertex set X and edge set $E(D) := \{\{x, y\} \in v\binom{X}{2} : D(x, y) < D(x, z) + D(z, y)$ for all $z \in X - \{x, y\}\}$. If D is a metric with $D(x, y) > 0$ for any two distinct points $x, y \in X$, then $D = D_{(G,w)}$ holds for the weighting scheme $w : E(D) \to \mathbb{R} : \{x, y\} \mapsto D(x, y)$, and $E(D){\subseteq}E$ holds for the edge set E of any graph $G = (X, E)$ for which a weighting scheme w with $D = D_{(G,w)}$ exists.

5. An example: graphs in sequence assembly

In *whole-shotgun sequencing*, sequence assembly can be performed by studying the *overlap graph* of a given collection of subsequences identified, for example, by PCR procedures: Given a finite set A of "letters", a string $\alpha := a_1a_2 \ldots a_N$ of length N, a positive integer $k < N$, and a collection $\mathcal{C}$ of subsequences of length k of the form $a_{i+1}a_{i+2} \ldots a_{i+k}$ of α, the problem is to reconstruct α from the subsequences in $\mathcal{C}$. While it is obvious that this is not always possible (e.g., the sequences *abcabab* and *ababcab* have the same set of subsequences of length 3 – so this is not even necessarily possible if $\mathcal{C}$ consists of *all* subsequences of length k *and* if all of these are distinct), one can still try to find at least one, or even all, strings α that would be *compatible* with the given collection $\mathcal{C}$ of k-strings. To this end, one can proceed as follows: One considers the associated *overlap graph* $G = G(\mathcal{C})$ whose vertices are the strings in $\mathcal{C}$ and whose edges are the pairs $a_1 \ldots a_k$ and $b_1 \ldots b_k$ of strings in $\mathcal{C}$ for which $a_2 \ldots a_k = b_1 \ldots {}_{k-1}$ holds (note that these edges come with a *preferred* direction, that is, that from $a_1 \ldots a_k$ to $b_1 \ldots b_k$). The task is to find a shortest path in that graph that respects directions and visits every vertex at least once. This is a typical problem in the important

area of *graph algorithms*, which, though unfortunately much too extensive to be covered in this article, still relies strongly on the concepts collected above.

6. Discussion

The above concepts and facts provide a highly flexible framework for dealing with complex data (in particular, discrete data with large degrees of freedom) such as collections of genetically related sequences, interaction patterns of biomolecules, and/or biochip data. Genomics, proteomics, toponomics, and metabolomics all rely on comparative data analysis and, hence, on the analysis of relationships encoded by coincidence or, at least, (dis)similarity. References could easily fill many pages. However, endowed with a solid understanding of the concepts and constructions presented above, most of their applications within these contexts should be sufficiently transparent or, at least, accessible.

Algorithms for sequence errors

Martti T. Tammi
Karolinska Institutet, Stockholm, Sweden
National University of Singapore, Singapore

The current state-of-the-art sequencing relies on the Sanger dideoxy chain termination method (Sanger *et al*., 1977). The method is based on a DNA synthesis process controlled by adding labeled dideoxy terminators, ddNTPs, into a polymerase reaction. DNA polymerases copy single-stranded DNA templates by incorporating nucleotides at the 3′ end of a primer annealed to the template DNA. The polymerase grows a new DNA strand by adding a nucleotide to the 3′-hydroxyl group at the growing end. The Sanger method exploits the fact that DNA polymerases are able to incorporate nucleotide analogs, such as dideoxynucleotides, ddNTPs, and fluorescently labeled terminators. ddNTPs are nucleotides that lack the 3′-hydroxyl group, while the label of the terminators block the 3′-position. By adding terminators, along with ordinary dNTPs, to the reaction, the elongation process is terminated once a terminator is incorporated. Since each terminator carries a different fluorescently colored label, we will be able to tell at which nucleotide the elongation was terminated. Several rounds of elongation will generate fragments of all sizes. These fragments are subsequently size-ordered by electrophoresis, and the nucleotide sequence can be read by detecting fluorescence after the labels are excited by a laser beam. This analysis is routinely performed in automatic sequencers, which usually utilize capillary electrophoresis.

Automatic sequencers produce so-called electropherograms or chromatograms (Figure 1), which are analyzed by specialized base-calling software (Ewing *et al*., 1998; Andrade and Manolakos, 2003; ABI, 1996) to determine the nucleotide sequence of the original template. The peak height is related to the number of fragments, which have the same length and end with the same nucleotide. The x-axis in a chromatogram is the time when the subpopulation has arrived to the detector of the sequencer. Depending on the terminators used, a specific mobility shift correction may be necessary, due to differences in migration caused by the different labels.

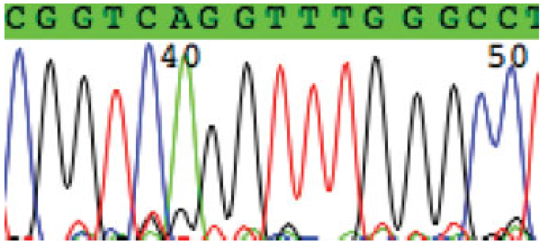

Figure 1 A section of a chromatogram produced by an automatic DNA sequencer. There are four different traces: Red for T, black for G, green for A, and blue for C. The x-axis is the time line when a subpopulation passes the detection point. The peak height is related to the number of fragments passing the detection point

Ideally, peaks in chromatograms for all four traces, one for each base, would be Gaussian-shaped and distributed evenly with no background noise. In real life, many factors perturb the signal detection, which make the base-calling procedure challenging and occasionally error prone. Some of the most important factors are:

1. In the beginning of the chromatogram, large and noisy peaks appear owing to unincorporated dyes, usually roughly the first 10 to 30 bases (Figure 2).
2. Toward the end of the chromatogram, peaks will be less evenly spaced and lumpy caused by diffusion of the fragments in the gel and by the loss of resolution due to the decrease in the difference of the relative mass of the fragments (Figure 2).

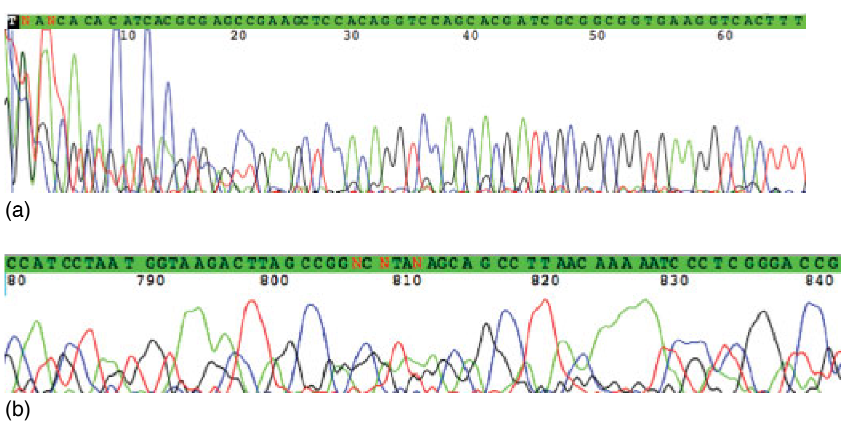

Figure 2 In the beginning of the chromatogram, large and noisy peaks appear because of unincorporated dyes. The first 66 positions are shown in (a). The peak height gets smaller toward the end of the chromatogram due to decreasing quantity of ddNTPs. The peaks may also be lumpy and unevenly spaced, which is caused by diffusion and the loss of resolution. Toward the end, the relative difference of the mass of the fragments decreases. The last 780–841 positions are shown in (b)

3. Toward the end of the chromatogram, the peak height gets smaller due to decreasing quantity of terminators relative to dNTPs.
4. The peaks may be compressed as a result of the formation of secondary structures in DNA fragments, such as hairpins. This is particularly common in GC-rich sequences.
5. Primer-dimer formation may cause false stops.
6. Uneven quantity of fragments may in some cases cause problems (ABI, 1996).

Thus, a base may be erroneously called, uncalled, or missed. These errors result in substitutions, deletions, and insertions of nucleotides respectively. Several attempts have been made to improve the quality of base calling (Ewing *et al*., 1998; Andrade and Manolakos, 2003; Davies *et al*., 1999; Brady *et al*., 2000; Giddings *et al*., 1998). It is, however, unlikely that the sequence data will ever become error free. Thus, it is necessary to try to improve the data quality using downstream methods. The latter include redundant sequencing, where the same region is sequenced several times, estimation of error probabilities, and error-correction methods.

In the shotgun sequencing method, the same genomic region is routinely sampled 5 to 10 times. This will increase the reliability of the data, since each base is sequenced several times and a so-called consensus sequence may be computed from the multiple alignments of the redundant sequences (Figure 3).

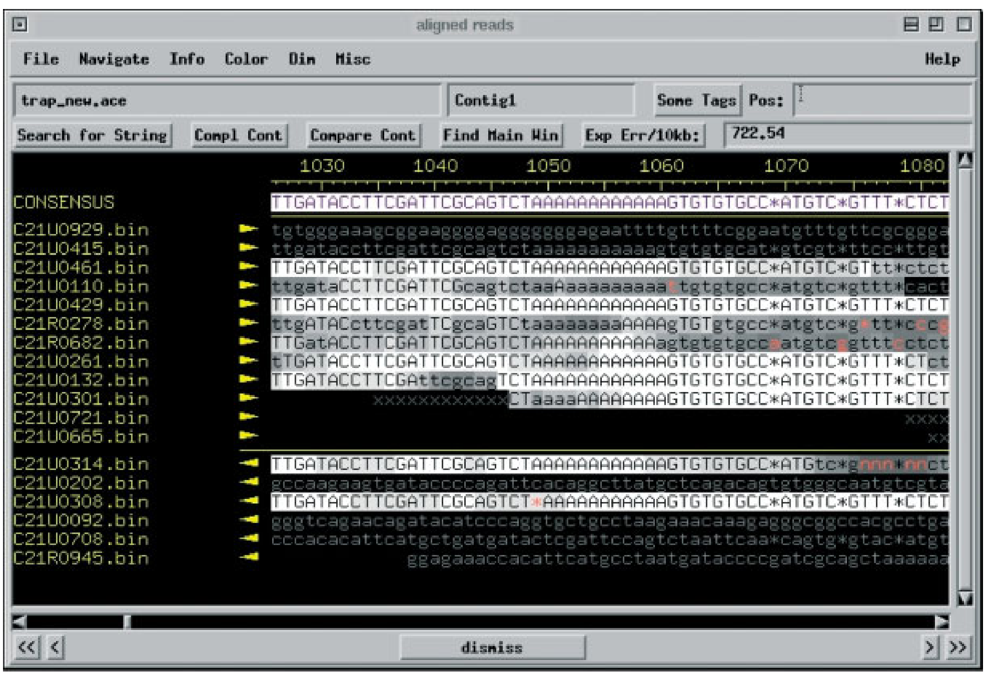

Figure 3 In a multiple alignment, a consensus sequence may be computed. A section of an alignment is shown in the Consed editor (Gordon *et al*., 1998). The numbers at the top are contig positions, followed by the consensus sequence and the reads. On the left are the read names, and arrows show the direction of the reads. The line in the middle separates the two DNA strands

Estimation of error probabilities of called bases is a powerful method to cope with sequencing errors. Many early base-calling algorithms estimated confidence values (Giddings *et al*., 1993; Giddings *et al*., 1998; Golden *et al*., 1993). Lawrence and Solovyev (1994) performed an extensive study and defined a large number of chromatogram parameters and analyzed them to determine which are most effective in distinguishing accurate base-calls. The base-calling program Phred (Ewing *et al*., 1998) is widely used today because of its ability to estimate the probability of an error in a base-call. Phred quality values have become the de facto standard within the sequencing community (Richerich, 1998). The quality values are logarithmic and range from 0 to 99. They are defined as follows:

$$q = -10.1\text{g}P \tag{1}$$

where q is the quality of the base-call and P is the estimated error probability of the call. The range of the Phred quality values is wide. For example, a quality value 10 means that in average one out of 10 calls is wrong and a value of 60 means that in average one out of a million base-calls is in error. In a typical sequence read, the quality is usually lowest toward the end of the reads as described above.

By characterizing signal traces in chromatograms and assigning parameter values to base-calls in sequences from an already known nucleotide sequence, it is possible to compare the output from a base-calling program to a benchmark data set. The relation to the frequency of base-calling errors can now be related to the parameter values calculated for each base-call. This can be used to estimate error probabilities in an unknown sequence by comparing parameter values of the known error frequencies. Phred uses a lookup table containing 2011 lines to set quality values. However, Phred does not provide any probabilities of missing base-calls or probabilities for any of the three other uncalled bases.

A widely used fragment assembly program, Phrap (**http://www.phrap.org**, 2005) utilizes Phred quality values. Phrap does not perform error correction, but uses a statistical framework to determine read overlaps. The quality values are also used in the computation of the consensus sequence, in most cases resulting in a more reliable sequence. Phrap assigns error probabilities to the consensus sequence itself, which helps to pinpoint problematic areas in assemblies.

The key problem in fragment assembly is the correct assembly of reads sampling repeated regions. The original genome sequence is reconstructed from short, redundantly sampled reads by using the criteria of similarity in the sequence. Similar reads are aligned together into multiple alignments, which form contiguous sequences, so-called contigs. In general, genomic sequences contain many repeats that may be identical or almost identical, and it is extremely difficult to distinguish the differences between reads originating from different repeated regions from sequencing errors. This is especially true when the difference between repeat copies is below 3%. Note that the error rate in sequencing varies and may be up to 11%. However, reads are normally trimmed at the ends to reduce errors, and an average remaining sequencing error in trimmed reads is somewhere around 1–2%. Error correction would reduce this problem.

Currently, there are three software tools that perform error correction on shotgun sequences: MisEd (Tammi *et al*., 2003), EULER (Pevzner *et al*., 2001), and

AutoEditor (Gajer *et al*., 2004), each of which use a different approach to the problem.

MisEd creates multiple alignments of shotgun reads. In this approach, the errors are corrected by first detecting differences between repeated reads using a statistical approach described by Tammi *et al*. (2002). If the multiple alignments are properly constructed, all the remaining differences must be sequencing errors. MisEd corrects these simply by converting the remaining differences to agree with the consensus base. In alignments that solely consist of nonrepeated or unique reads, all observed differences should be errors, since these reads sample the same genomic region. In the shotgun sequencing approach, the same genomic regions are generally sampled 5 to 10 times in average, and it is fairly easy to assemble reads originating from nonrepeated regions of the genome.

Patterns of differences between reads can be observed by creating multiple alignments of all similar reads in a shotgun project. An example of such an alignment is shown in the Figure 4, in which reads from different, very similar genomic repeats are aligned. Differences between reads caused by sequencing errors appear random, but a systematic appearance of differences between reads originating from separate repeat copies can be observed. In fact, the appearance of sequencing errors can be approximated by the Poisson process. This phenomenon is utilized in the MisEd program, which computes the probability of a random appearance of such patterns. If the estimated probability of observing a pattern of differences by random sequencing errors is very low, below a certain threshold, the differences are considered to be true differences. These differences are labeled as Defined Nucleotide Positions (DNPs). Errors are corrected by converting all, but DNPs into the same base as the consensus base in the alignment.

EULER or EULER assembler is a shotgun assembly program, which contains an error-correction step. In this approach, the reads are chopped into small pieces, roughly 40-bases long, and so-called spectral alignments using these short fragments are constructed (Figure 5). These alignments of short fragments display a similar pattern of differences between fragments as multiple alignments constructed of whole-shotgun reads. Sequence errors appear sporadically and real differences between repeats appear more systematically, that is, more frequently in a column of the alignment. The count of short fragments aligned on each read is analyzed

```

     ATTGAAGCATCTCATGACGCGATCAACGAT
```

Figure 4 An example of an alignment of reads originating from repeat copies located in different genomic regions. The systematic appearance of differences can be observed for the real differences between repeat copies. The appearance of sequencing errors is sporadic. The repeat copies are marked as R1, R2, and R3

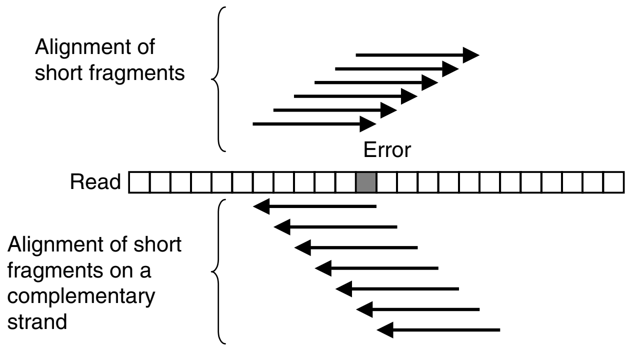

Figure 5 A schematic illustration of a spectral alignment of short fragments of reads. An error in a read affects the number of short read fragments, which can be aligned exactly on a read and its complementary strand

and erroneous positions determined by the number of aligned short fragments (Figure 5). The EULER program does not rely on any statistical framework. Certain parameters are used to set the lower threshold of the number of differences accepted as sequencing errors. All bases below this limit are considered to be caused by sequencing errors and converted to the consensus base. The parameters are user definable.

AutoEditor combines an approach of realigning shotgun reads to the consensus sequence and reexamination of the chromatogram data produced by sequencers. By recalling suspicious base-calls, AutoEditor is effectively able to correct errors. However, surprisingly, this program does not yield better results than the two previously described methods, even though chromatogram data is reexamined.

Sequencing errors are the root of the challenges in genome sequencing, particularly in combination with repeated genomic regions. They cause many errors in genome assemblies, and finishing of the projects requires a lot of manual labor. Perhaps we will see many automated finishing tools utilizing some kind of error correction/analysis methods in the near future.

Basic Techniques and Approaches

Polymorphism and sequence assembly

Brinda K. Rana, Douglas W. Smith and Nicholas J. Schork
University of California, San Diego, CA, USA

1. Introduction

Worldwide research efforts to characterize the human genome, such as the Human Genome Project (*see* Article 24, **The Human Genome Project**, Volume 3), the ENCODE project, and the International HapMap Project, along with advances in DNA sequencing technologies, have produced an enormous amount of DNA sequence information. This information is becoming available in public databases and will allow researchers to identify and characterize naturally occurring variations in the human DNA sequence across individuals. Such genetic variation, that is, differences in DNA sequence among a group of individuals or between populations, occurring with frequency $>1\%$ is known as genetic *polymorphism*. Sources of polymorphisms within DNA sequence include variable numbers of tandem repeats (VNTRs) such as microsatellite repeats and short tandem repeats (STRs), small insertions and deletions of sequence (in/dels), gene copy number variation (Sebat *et al*., 2004; Fredman *et al*., 2004), and single-nucleotide polymorphisms (SNPs) (Kwok *et al*., 1994). SNPs are the most abundant form of genetic polymorphisms found in the human population and have become a focal point in the study of the genetic basis of multifactorial diseases and traits (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2), interindividual differences in response to therapeutic drugs ("pharmacogenomics"), and human evolutionary and population history (*see* Article 71, **SNPs and human history**, Volume 4). This article will outline sequencing-based molecular and bioinformatics approaches for the identification of SNPs in the human population. Although approaches discussed can be extended to study polymorphism in other organisms and/or other types of polymorphism, the sequencing-based identification and scoring of repeats and in/dels can be more challenging than for SNPs.

As noted, SNPs are the most simple and abundant form of a genetic polymorphism and occur along a stretch of DNA sequence when one of the four nucleotides that contain the base adenine(A), cytosine(C), thymine(T), or guanine(G) is replaced by one of the remaining three nucleotides. A SNP that occurs between the purines (A, G) or pyrimidines (C,T) is known as a transition and constitutes two-thirds

of all SNPs (Iida *et al*., 2001a,b,c; Freudenberg-Hua *et al*., 2003); a transversion occurs between a purine and a pyrimidine.

By 2001, data arising from the public Human Genome Project identified over one million SNPs averaging one SNP every 1331 bp in comparison of two human chromosomes drawn from an ethnically diverse sample of individuals (The International SNP Map Working Group, 2001). A combination of polymorphisms that are closely linked on a single chromosome and that are inherited together on a single maternal or paternal chromosome is termed a *haplotype*. SNPs have become instrumental in defining haplotype “blocks” that reflect stretches of genome encompassing multiple SNPs with alleles that appear to be inherited together in the human genome (The International HapMap Consortium, 2003; **http://www.hapmap.org**).

2. In silico SNP discovery

Numerous SNPs were initially detected by comparing sequences from independent sources of mRNA and expressed sequence tags (ESTs) that had either been deposited in the public domain (dbEST; Boguski *et al*., 1993) or generated by large sequencing projects (Marth *et al*., 1999; Irizarry *et al*., 2000; Useche *et al*., 2001). Over 48 000 SNPs were identified through the use of purely computational and bioinformatic tools. This “in silico” mining of SNPs consist of simple comparisons of extant DNA sequence obtained from different sources, individuals, or investigators. These SNPs have been integrated into public databases such as dbSNP at the National Center for Biotechnology Information (NCBI). Owing to the potential errors in sequence information, either introduced by Taq polymerase during PCR or computational errors associated with base calling algorithms necessary for interpreting the results of sequence assays, in silico–defined SNPs should be validated through direct sequencing to confirm their existence in the human population. NCBI’s dbSNP catalogs over 900 000 SNPs (Sherry *et al*., 2001) as well as small in/dels, and retroposable element insertions; other SNP databases contain SNPs specific to particular ethnic populations (e.g., JSNP), while others catalog SNPs involved in diseases (e.g., HGVSNP) (Table 1). SNP databases are a good resource for investigators to verify SNPs that they have identified in their own sequencing studies, for choosing loci for further sequencing studies, and

for selecting SNPs to genotype for association studies. However, the investigator should be aware that SNPs contained in these databases have been obtained through various techniques, including in silico approaches, and a number of these SNPs remain unvalidated while others may have been missed because of the technique used or the population studied. Recent studies have investigated the quality of SNP databases (Jiang *et al*., 2003; Reich *et al*., 2003; Mitchell *et al*., 2004).

3. Targeted polymorphism discovery at candidate loci

Computational mining of SNPs from available DNA sequence databases has led to the identification of only a fraction of the SNPs' existing in the population; rare SNPs having low allele frequencies, or SNPs that are unique to a specific population ("population specific SNPs") are less likely to be found by these approaches (Kruglyak and Nickerson, 2001). Direct sequencing of a population of individuals followed by a comparison of the resulting sequences through multiple sequence alignment procedures is the most reliable of methods for identifying SNPs and other polymorphisms.

Fluorescence-based sequencing has become an important tool for such polymorphism discovery studies (see Griffiths *et al*., 1996, for a description of available sequencing methods). Figure 1 summarizes the steps in sequence-based polymorphism discovery following the selection of samples for sequencing: Polymerase chain reaction (PCR) amplification of locus in samples; sequencing of PCR products from forward and reverse directions; base calling, contig assembly, and polymorphism detection by sequence analysis software; and finally visualizing aligned sequence chromatograms for polymorphism identification and heterozygous base calling.

3.1. Samples

The choice of DNA samples depends on the ethnic population of interest, trait, or disease being studied, and the power desired to detect a polymorphism of a certain frequency. For example, sequencing 50 individuals (100 chromosomes) will enable the identification of SNPs that are at least 1% in that population with high (>80%) confidence. The frequencies of a number of SNPs are known to vary in different populations. Thus, limiting studies to a single population will reduce the chance of identifying SNPs common in other populations that are frequent or rare in the studied population. Therefore, to identify disease-associated variants, sequencing DNA from a pool of affected individuals is ideal, and ethnic background should be considered (*see* Article 75, **Avoiding stratification in association studies**, Volume 4).

However, to maximize the probability of finding a variant in the general human population, ethnic diversity panels is the best strategy. To facilitate the discovery of genetic variants in the entire human population, the National Human Genome Research Institute (NHGRI) of NIH, in conjunction with the Centers for Disease Control and Prevention, the National Institute of Environmental Health Sciences, and individual investigators, has assembled a DNA Polymorphism Discovery Resource consisting of DNA samples from 450 unrelated individuals from the United States, with ancestry from major regions of the world (Collins *et al*., 1998).

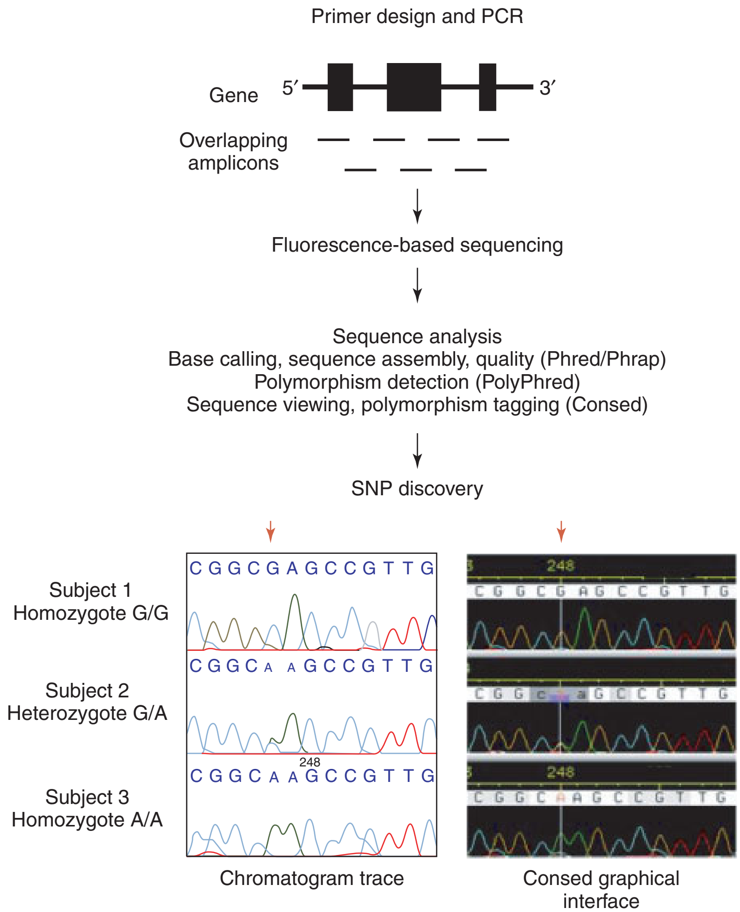

Figure 1 Targeted polymorphism discovery at candidate loci. PCR primers are designed to generate overlapping fragments (amplicons) of DNA to accommodate sequencing the entire gene of interest. Fluorescence-based sequencing generates chromatograms that are analyzed through the software package of choice to facilitate polymorphism discovery. Consed tags an SNP at position 248. A red arrow above both chromatogram views indicates the location of the discovered SNP. Subjects 1 and 3 are homozygous for nucleotide G and A, respectively. Subject 2 is determined to be heterozygote based on overlapping G and A traces that have approximately one-half the amplitude of either homozygote peak

These samples, as well as the NIH Diversity Panel, are available from the Coriell Institute for Medical Research (**http://coriell.umdnj.edu**) in collaboration with the National Institute of General Medical Sciences (**http://locus.umdnj.edu/nigms/**).

3.2. *PCR amplification of DNA samples and sequencing*

Forward and reverse sets of oligonucleotide primers for PCR amplification of a desired region of the genome are designed on the basis of gDNA sequence obtained, for example, from GenBank (NCBI). Messenger RNA sequence does not contain

intronic sequence found in gDNA, so care should be taken when designing PCR primers on the basis of these edited sequences for gDNA templates. Depending on the sequencing assay and instrument used, PCR primers should be designed to amplify approximately 600–1000-bp fragments. A popular software for optimizing primer design is Primer3 written at the Whitehead Institute (**http://www-genome.wi.mit.edu/cgi-gin/primer/primer3_ www.cgi**); PCR-Overlap© (**http://droog.gs.washington.edu/PCR-Overlap.html**; ©1998-1999 University of Washington, Rieder MJ and Nickerson DA) and The PCR Suite (**www.eur.nl/gff/kgen/primer/**; van Baren and Heutink, 2004) are free software packages that extend Primer3 by facilitating the design of PCR primers to generate overlapping fragments of DNA for loci that are too large to be accommodated by a single PCR fragment. Overlapping at least 100 bp on each end of the PCR fragment will reduce the chance of missing SNPs located in the primer region or on the ends of the PCR-amplified fragments (amplicons), which generally do not sequence well by fluorescence-based methods. Following the PCR amplification reaction, amplicons are purified and prepared for sequencing. The set of forward and reverse PCR primers for each amplicon can be used as sequencing primers to sequence from both ends of the amplicon. Alternatively, sequencing primers can be designed on the basis of other sequences contained in the amplicon.

3.3. Sequence analysis

Accurate and efficient sequence analysis for fluorescence-based sequencing requires software for base calling, sequence assembly, polymorphism detection, and sequence visualization. Two examples of reliable software packages for sequence analysis are MacVector (Rastogi, 2000) and the Phred/Phrap/Consed suite of sequence analysis software, the latter of which we present here in more detail. Phred is used to automate base calling including accuracy assessments of base calls (Ewing *et al*., 1998; Ewing and Green, 1998); Phrap assembles sequence fragments of multiple amplicons on the basis of a representative sequence of the locus; and Consed enables the visualization of sequence alignments as well as the original fluorescent graphical data (“chromatogram traces”) from which the base calls were made (Gordon *et al*., 1998). Polymorphisms called by sequence analysis software should also be reverified manually using a graphical interface such as Consed.

3.4. Heterozygous base calling

Since humans are diploid (have two copies of each chromosome – one inherited from the mother and one inherited from the father), a DNA sequence from gDNA template represents both copies of the chromosome. An individual is *heterozygous* at a polymorphic site when two different alleles (two different bases for a SNP) exist at that site. It can be difficult to accurately identify heterozygous sites because of the variability in fluorescence signals and inconsistency of base calling at these sites. The detection of heterozygous sites when comparing sequence traces of homozygotes with heterozygotes is based on the observation of a significant drop in peak height (to approximately one-half) along with the presence of a second,

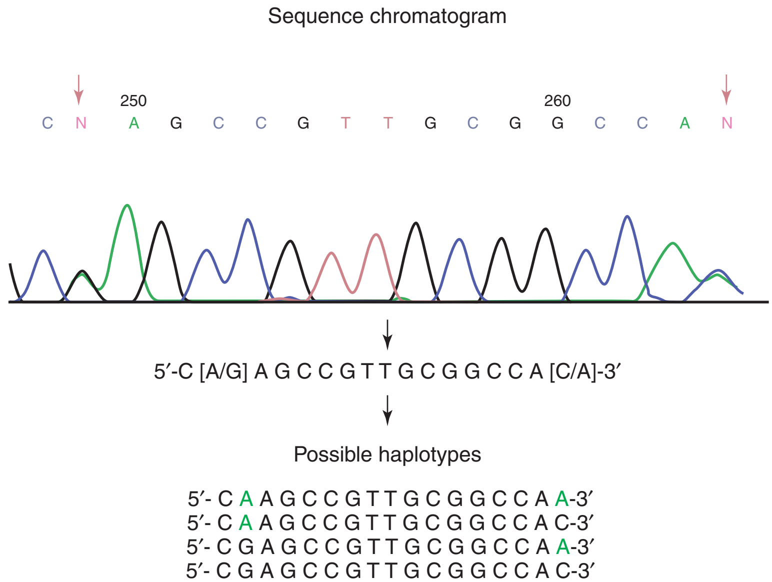

Figure 2 Complexity of haplotype determination in diploid organisms. A segment of continuous sequence from a human subject has two SNP sites, position 249 G/A and position 264 A/C. There are four possible combinations of two SNPs representing four possible haplotypes. All four haplotypes or only a subset may be represented in the human population. Further analysis is needed to determine the true haplotypes of this subject

overlapping peak in heterozygotes. PolyPhred is one of the most reliable software packages available for automated detection of heterozygous sites (Nickerson *et al*., 1997). Chromatogram traces from multiple individuals may be compared, for example, with Consed, to help assess difficult heterozygous calls.

3.5. *Verifying rare genetic variants*

The advantage of polymorphism discovery studies on a large number of samples is being able to identify rare variants in the population. However, genetic variants observed only once should be verified through reamplification from original gDNA template followed by sequencing to rule out the possibility of Taq polymerase induced or other sequence analysis errors.

3.6. *SNP haplotype assembly*

Because of the predominant diploid character of the human genome (see above), SNP identification in fragmented sequences introduces an algorithmic problem for assembly of multiple SNP genotypes into true haplotypes. If there are two or more SNPs in a fragment of genomic sequence, it is impossible to determine the haplotype just from that sequence (Figure 2). The most reliable method for delineating haplotypes is to clone a DNA fragment containing multiple SNP sites

into a bacterial plasmid vector. After transformation of cloned vector into bacteria, a single colony representing the sequence from one chromosome can be chosen for sequencing. (see Griffiths *et al*., 1996, pp. 424–432). The sequence of the fragment representing the other chromosome can be accurately inferred on the basis of the sequenced chromosome fragment. When multiple individuals are studied, haplotyping each individual using the cloning method is time consuming and costly. In such cases, algorithms that statistically infer haplotypes may be a more efficient approach (Table 2). When the number of individuals is large or family data exists, such statistical inference can be reasonably accurate (Salem *et al*., 2005).

4. Conclusion

Polymorphism discovery relies heavily on sequencing-based methods of detection as presented here, however, other nonsequencing-based alternatives have been used. For example, the denaturing high-performance liquid chromatography (dHPLC) method, which utilizes the different mobility of homo- versus heteroduplexes of PCR amplicons during liquid chromatography under partial denaturing conditions, has successfully been employed for SNP discovery (Han *et al*., 2004). Such nonsequence-based genotype detection methods must be followed up with sequencing to determine the actual sequence change of the variant. Once SNPs and other polymorphisms have been discovered, one of the alternate high- or moderate-throughput strategies for genotyping large numbers of individuals can be employed as these will be more efficient than direct sequencing when the investigator is interested in typing subjects at single polymorphic sites (reviewed in Kwok, 2001; Gut, 2001).

Introductory Review

Prokaryotic gene identification *in silico*

Mark Borodovsky and Rajeev Azad
Georgia Institute of Technology, Atlanta, GA, USA

Statistical methods for the identification of protein-coding regions in prokaryotic genomes have been the main tools for gene annotation since the start of genomic era. The pioneer papers describing gene-recognition algorithms appeared in press in the 1980s (Fickett, 1982; Staden, 1984; Gribskov *et al*., 1984; Almagor, 1985; Claverie and Bougueleret, 1986; Borodovsky *et al*., 1986a, b, c; Fichant and Gautier, 1987). These methods were using the so-called intrinsic information, statistical patterns in nucleotide ordering, characteristic for protein-coding and noncoding regions observed in a single DNA sequence. Methods utilizing the so-called extrinsic information embodied in common or similar sequences conserved in evolution and identified by comparison of DNA or proteins of different species were developed later (Gish and States, 1993; Robison *et al*., 1994). With the fast accumulation of DNA and protein sequences, use of extrinsic information has gained more attention and methods combining both intrinsic and extrinsic information have appeared (Borodovsky *et al*., 1994; Frishman *et al*., 1998).

Development of *ab initio* gene recognition algorithms that use intrinsic information generally follows three steps. At the first step, statistical measures (e.g., G + C composition) that may help distinguish sequence types (e.g., protein-coding vs. noncoding) are determined. At the second step, the statistical models are built for sequences of all types. At the third step, the models are integrated into a statistical pattern recognition algorithm.

In 1992, in a comprehensive review, Fickett and Tung analyzed more than 20 types of statistical measures of protein-coding regions and singled out as the most informative ones the frame-dependent (positional) hexamer frequencies (Fickett and Tung, 1992).

Introduced in 1986, inhomogeneous Markov chain models of a protein-coding region (Borodovsky *et al*., 1986b) have been a rigorous mathematical framework for using positional oligonucleotide frequencies. This model combined with a homogeneous Markov model of noncoding sequence in a Bayesian algorithm possesses a significant predictive power, as was demonstrated by the GeneMark gene finding program (Borodovsky *et al*., 1986c; Borodovsky and McIninch, 1993).

The GeneMark algorithm identifies protein-coding regions in both DNA strands by analyzing only one of them. To accomplish this, a Markov model of a DNA sequence complementary to a gene on the opposite strand (“shadow” model)

is added to the already-mentioned models of "direct" protein-coding sequence and noncoding sequence. The algorithm outline is as follows. Given the first-order Markov chain model, the probability that a DNA sequence segment, $S = \{s_1, s_2, \ldots, s_n\}$ (n is a multiple of 3), comes from a protein-coding region with s_1 being the first nucleotide of a codon (event E_1 or frame 1 setting) is given by the formula $P(S|E_1) = P^1(s_1) * P^1(s_2|s_1) * P^2(s_3|s_2) * P^3(s_4|s_3) * \cdots * P^2(s_n|s_{n-1})$ Here $P^i(s_1)$ is the probability for s_1 to be situated in frame i and $P^i(s_k|s_{k-1})$ is the transition probability of s_k to succeed s_{k-1} situated in frame i. Similar expressions for $P(S|E_i)$, $i = 2$ to 7 could be written for the remaining six events, which correspond to sequence S coming from the coding region in frame 2 and frame 3 settings (E_i, $i = 2, 3$); from a region complementary to a gene in frames 4, 5, and 6 (E_i, $i = 4, 5, 6$), here the shadow model is used; and from a noncoding region (E_7), here the noncoding model is used (and no frame setting is needed). Thus, the determined probabilities $P(S|E_i)$ are used to compute an *a posteriori* probability for each E_i to be associated with observed sequence S, $P(E_i|S) = \frac{P(S|E_i)*P(E_i)}{\sum_i P(S|E_i)*P(E_i)}$. Here $P(E_i)$ is the *a priori* probability of event E_i. It is possible to consider the GeneMark algorithm as an approximation to the forward–backward algorithm, known in the theory of hidden Markov models (HMM) (Rabiner, 1989), which computes the *a posteriori* probability of a hidden (functional) state underlying a given observed state (a nucleotide) in a particular sequence position (Azad and Borodovsky, 2004a). This interpretation could be unexpected as the forward–backward algorithm is used frequently at a training step for an HMM-based algorithm. Here we certainly deal with the prediction step. Still, we may consider the value of $P(S|E_i)$ computed by GeneMark for a short DNA segment S (within a sliding window) to be an approximation to the value of an *a posteriori* probability for the hidden state E_i for a nucleotide position in the middle of segment S computed by a rigorous forward–backward HMM algorithm, given the entire model of states and transitions.

Given the notion that genes in prokaryotic genomes are continuous open reading frames (ORFs), though by far not all ORFs are genes, the GeneMark program computes a scoring statistics for each ORF in the genomic sequence. This score is the average value of the *a posteriori* probabilities of the events E_i (for one and the same i defined by the ORF) for the short subsequences of the ORF in question. If this value is larger than a certain threshold, then the ORF is predicted as a gene.

It can be shown that Markov models of higher orders perform better for gene recognition than the first-order ones. The difficulty though may arise with the high-order model parameter estimation (model training). If the length of DNA sequence available for training is limited, an attempt to derive parameters of Markov models of high order may end up in overfitting of at least a fraction of the model parameters to the training data. However, the attempt to recover the informative parameters of the high-order model and combine them with informative parameters of lower-order models may result in better predictive ability (Jelinek *et al*., 1980). Such combined (interpolated) models have been used in the Glimmer algorithm (Salzberg *et al*., 1998; Delcher *et al*., 1999). Their parameters are defined by recursive equation, $P^{IMM}(b|c_k) = \lambda(c_k) * P(b|c_k) + (1 - \lambda(c_k)) * P^{IMM}(b|c_{k-1})$. Here $P^{IMM}(b|c_k)$ is the interpolated transition probability of a nucleotide b to succeed k-mer c_k,

$P(b|c_k)$ is the transition probability as defined in a regular Markov chain model, and $\lambda(c_k)$ is the interpolation parameter corresponding to k-mer c_k, $0 \leq \lambda(c_k) \leq 1$. It is reasonable to expect that if the frequency of c_k in the training sequence is sufficiently high, then $\lambda(c_k)$ should be close to 1; for low frequency c_k, $\lambda(c_k)$ should be close to 0. However, accurate estimation of $\lambda(c_k)$ is a critical issue and several approaches have been proposed to address it (Salzberg *et al*., 1998; Potamianos and Jelinek, 1998; Azad and Borodovsky, 2004b).

The Bayesian framework was further generalized by using HMM, which have been used in several prokaryotic as well as eukaryotic gene prediction algorithms developed in the last decade (Krogh *et al*., 1994; Yada and Hirosawa, 1996; Lukashin and Borodovsky, 1998; Yada *et al*., 2001; Larsen and Krogh, 2003; Burge and Karlin, 1997; Krogh, 2000; *see also* Article 14, **Eukaryotic gene finding**, Volume 7, Article 21, **Gene structure prediction in plant genomes**, Volume 7, and Article 26, **Dynamic programming for gene finders**, Volume 7). In an HMM, the gene recognition problem is reformulated as a problem of finding the most likely sequence $H = \{H_1, \ldots, H_n\}$, where H_i stands for a hidden state, for example protein-coding or noncoding, underlying a given DNA sequence $S = \{s_1, \ldots, s_n\}$. Hidden (functional) and observed (nucleotide) states are connected in an HMM by probabilistic (Markov chain type) dependencies. If HMM structure and parameters are defined, then for a given sequence S, the Viterbi algorithm solves the problem stated above and finds the most likely state sequence $H*$ by maximizing the conditional probability $P(H|S)$ with respect to H.

The first HMM-based gene prediction algorithm, ECOPARSE, was described by Krogh *et al*. (1994). ECOPARSE and the later developed GeneHacker (Yada and Hirosawa, 1996) are based on a classic HMM, with a hidden state emitting one nucleotide triplet (codon) from the protein-coding state and emitting one nucleotide from noncoding state. In the GeneMark.hmm program (Lukashin and Borodovsky, 1998), a hidden state is assumed to emit a whole sequence of observed states (nucleotides), with length specified by a probability distribution. The homogeneous and inhomogeneous Markov models (earlier utilized in GeneMark) are used as submodels of the main HMM to describe these emitted nucleotide sequences. The HMM architecture of GeneMark.hmm also included hidden states for rare “atypical” (e.g., horizontally transferred) genes, along with states for abundant native “typical” genes. Note that GeneMark.hmm and GeneMark possess complementary properties as the former implements the generalized Viterbi algorithm dealing with the sequence as a whole and the latter approximates the forward–backward algorithm, revealing local features of gene organization. Particularly, the *a posteriori* probability graphs generated by GeneMark in six reading frames help in detecting frameshifts (local irregularities) in the sequence that mainly occur because of sequencing errors.

Extrinsic information could be used in gene finding algorithms in several different ways. Early extrinsic algorithms used straightforward similarity search on protein level, that is, BLASTX, to identify ORFs whose protein products score statistically significant hits to known proteins. More recent algorithms combine extrinsic and intrinsic information. For instance, parameters of the gene models in the ORPHEUS program (Frishman *et al*., 1998) are estimated from ORF sequences whose protein products show significant similarity to known proteins.

As an indicator of the genetic code presence, ORPHEUS is using the statistic $\Omega = R(a_1a_2 \ldots a_n) - \max\{R(b_1b_2 \ldots b_n), R(c_1c_2 \ldots c_n)\}$, where $R(a_1a_2 \ldots a_n)$, is the normalized value (in units of standard deviation) of the quantity $\sum_{i=1}^{n} \log f(a_i)$. Here $f\ (x_\mathrm{i})$ is the frequency of x_i codon and $(a_1 \ldots a_n)$, $(b_1 \ldots b_n)$, $(c_1 \ldots c_n)$ stand for the sequences of codons in three possible frames. Similar validation of a training set by using extrinsic data is implemented in the recent algorithm EasyGene (Larsen and Krogh, 2003). EasyGene scores sequence S of each ORF by computing a statistics $W = \log\left(\frac{P(S|M)}{P(S|N)}\right)$ where $P(S|M)$ and $P(S|N)$ are the probabilities of S being generated by HMM of a gene, M, and HMM of noncoding region, N, respectively. A rather unique feature of EasyGene is the assessment of the statistical significance of the computed score. The CRITICA algorithm (Badger and Olsen, 1999) uses both extrinsic and intrinsic approaches to assign scores reflecting protein-coding propensity to a DNA sequence fragment in each of the six possible frames. The score is a sum of two components: a comparative (extrinsic) score based on the relative identities of nucleotides and corresponding potential amino acids and noncomparative (intrinsic) score based on dicodon bias in real protein-coding frames. Shibuya and Rigoutsos (2002) developed Bio-Dictionary, a database of patterns called "seqlets" extracted from protein sequence databases. If the number of seqlets matching to the ORF protein product exceeds a predetermined threshold, the ORF is predicted as a gene. This approach was implemented in a gene prediction algorithm, called Bio-Dictionary Gene Finder (BDGF) (Shibuya and Rigoutsos, 2002). Finally, one of the most extrinsic information oriented programs GeneHacker Plus (Yada *et al*., 2001), an improved version of GeneHacker (Yada and Hirosawa, 1996), has an ability to include the results of similarity searches as restrictions in the Viterbi algorithm.

The exact determination of gene start position is an important part of prokaryotic gene identification task. The algorithms mentioned above, ECOPARSE, EasyGene, GeneHackerPlus, GeneMark.hmm, and Glimmer use ribosome binding site (RBS) models to improve accuracy of gene start prediction. A two-component RBS model is included in the HMM architecture of GeneMark.hmm and its parameters along with other model parameters could be derived by GeneMarkS (Besemer *et al*., 2001), the unsupervised training program implementing the expectation-maximization procedure. This procedure iterates predictions and model derivation to the point where the gene predictions made with updated models coincide with gene prediction in the previous step (i.e., till the convergence is reached). The convergence is facilitated by use of heuristic pseudocounts at the initial step of the procedure (Besemer and Borodovsky, 1999). Note that several of the above-mentioned algorithms have extensions for deriving models by unsupervised learning procedure, which are useful if one has to start analysis of a new genome. Assessment of the performance of gene finding algorithms has been far from simple issue due to the lack of sufficient number of experimentally validated genes. Even an ability of a program to reproduce correctly most of the genes annotated in GenBank will not provide conclusive evidence of the algorithm's high predictive power unless the test on experimentally validated genes would support this statement. Two parameters are usually used to measure the prediction accuracy: the percentage of genes in the test set that are correctly identified by the

algorithm (Sensitivity, Sn) and the percentage of predictions that match the genes in the test set (Specificity, Sp).

All above-mentioned programs have shown high performance with Sn and Sp values higher than 90% in majority of the tests that were done with regard to GenBank annotated sequences. Still there is a need to carefully design test sets for various prokaryotic species and assess the performance if one is interested in this issue in depth.

Currently, the largest number of experimentally validated genes is known for *Escherichia coli*. When 195 *E. coli* genes with their starts determined by N-terminal protein sequencing were used for accuracy tests, both GeneMarkS and EasyGene correctly identified above 93% of the gene starts (Larsen and Krogh, 2003). Similar results were observed when the same algorithms were tested on a larger set comprising 850 *E. coli* genes with validated start positions (Rudd, 2000) (see **http://bmb.med.miami.edu/EcoGene/EcoWeb/**).

The rather short history of development of the prokaryotic gene identification algorithms presents a picture of significant accomplishments. However, the perfectionist goal to identify by computer all protein-coding genes in a given genome without false-positives remains a challenge. The main part of this challenge is the flawless detection of short genes. Identification of atypical or laterally transferred genes is a closely related problem as genes from this group are frequently escaping detection. Further improvement of gene start prediction is another issue that remains to be addressed. However, continuation of strong efforts toward integrating intrinsic and extrinsic approaches should bring us closer to a point when the prokaryotic gene identification problem would be declared completely solved.

1. Introduction

Gene prediction is the process of inferring the sequence of the functional products encoded in genomic DNA sequences. In this chapter, we will review computational methods to predict protein-coding genes. These methods are usually limited to the prediction of the coding fraction of the genes and they ignore for the most part the prediction of the terminal 5′ and 3′ untranslated regions.

In the eukaryotic cell, the pathway leading from the DNA sequence of the genome to the amino acid sequence of the proteins proceeds in a number of steps. A gene sequence is first transcribed into a pre-mRNA sequence, this transcript is subsequently processed (i.e., capped, spliced, and polyadenylated), and the mature mRNA transcript is then transported from the nucleus into the cytoplasm for translation into a functional protein. A number of sequence motifs in the primary DNA sequence or in the intermediate RNA sequences are recognized along this pathway: promoter elements that indicate the site for the initiation of the transcription, splice sites that define the boundaries of the introns removed during splicing, and the initiation and termination codons that define the segment of the mature mRNA translated into protein. A natural approach is for computational gene-prediction methods to attempt to model these sequence motifs, and the mechanism by means of which they are recognized. However, known sequence motifs involved in gene specification carry not enough information to precisely elucidate eukaryotic gene structures, and current computational methods need to rely on additional information such as sequence compositional bias and similarity to known coding sequences. With the flowering of eukaryotic sequencing, genome comparisons have also recently emerged as a powerful approach for eukaryotic gene prediction.

In summary, gene-finding programs predict genes in genomic sequences by a combination of one or usually more of the following approaches:

1. analysis of sequence signals potentially involved in gene specification
2. analysis of regions showing sequence compositional bias correlated with coding function
3. comparison with known coding sequences (proteins or cDNAs)
4. comparison with anonymous genomic sequences.

The so-called ab initio or de novo gene predictors combine approaches 1 and 2. We will term here methods relying mostly in approach 3 as "homology-based" gene predictors, and those mostly based on approach 4 as "comparative" gene predictors. There is not, however, a widely accepted terminology, and, for instance, "comparative" gene predictors are often included within the "de novo" category to separate them from those methods relying on expression data (proteins or cDNAs). Moreover, as programs become increasingly complex, the frontiers between the different categories become very fuzzy, with systems existing nowadays that employ all of the strategies enumerated above.

In this article, we will first review methods to identify sequence signals and to capture the sequence composition bias characteristic of protein-coding regions. We will then describe how these methods are integrated in "ab initio" gene finders, and how these are extended into homology-based and comparative predictors.

2. Prediction of signals

Splice sites (donor and acceptor), translation initiation, and termination codons are the basic sequence signals involved in the definition of coding exons. Typically, these signals are modeled as position weight matrices (PWMs, see Figure 1). The coefficients in these matrices are the observed probabilities in known functional sites of each nucleotide at each position along the signal. Assuming independence between positions, PWMs can be used to compute along a genomic interval the probability of the sequence at a given position assuming that it corresponds to a functional site. Those positions in which this probability is much larger than the background probability of the sequence are typically predicted as potential functional sites. However, because of the degeneracy of the signals, usually many more sites are predicted to be functional than actually are.

To improve signal prediction, methods have been developed that relax the assumption of independence between adjacent positions. In the so-called first-order Markov or weight array model (Zhang and Marr, 1993), the probability of a nucleotide at a given position is conditioned on the nucleotide at the preceding position. Higher-order Markov models – in which the probability at one position is conditioned to a number of preceding positions – have also been considered (see, for instance, Salzberg *et al*., 1998). Dependencies, however, may not be limited to adjacent positions along the signal. Nonlocal dependencies are implicit in the maximal dependence decomposition (MDD) method (Burge and Karlin, 1997), which has been applied to the prediction of donor sites. More recently, methods based on Bayesian networks, and other probabilistic frameworks, that attempt to systematically recover all relevant dependencies between positions in sequence signals, have been developed for the prediction of splice sites (see, for instance, Castelo and Guigó, 2004). Machine-learning techniques, which capture nonlocal dependencies, have been applied to the prediction of sequence signals as well. The NetGene program (Brunak *et al*., 1991) is an early example of the application of neural networks (*see* Article 98, **Hidden Markov models and neural networks**, Volume 8) to splice site prediction. See Article 16, **Searching for genes and biologically related**

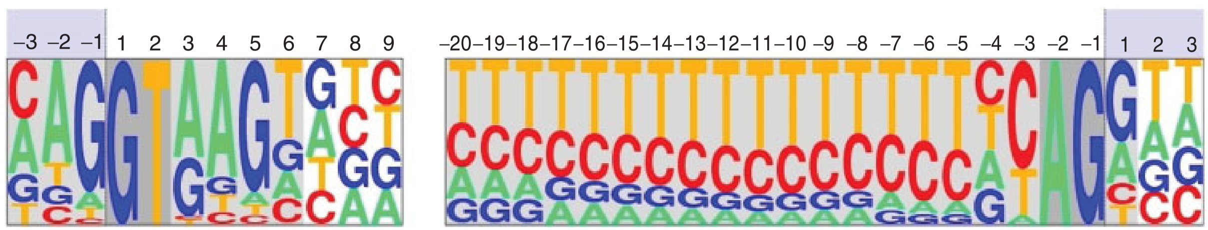

Figure 1 Sequence logo displaying the position weight matrices (PWMs) corresponding to the canonical donor and acceptor sites of U2 eukaryotic introns. The height of each letter at each position along the site is proportional to the frequency of the corresponding nucleotide as observed in real splice sites. The deviation from random composition can be used to develop methods to predict splice sites. Sequence logo obtained with the program pictogram (Burge *et al*., **http://genes.mit.edu/pictogram.html**)

signals in DNA sequences, Volume 7 and Article 28, **Computational motif discovery**, Volume 7 for a more in-depth review of methods to predict sequence signals.

Despite the variety of efforts, prediction of splice sites (and of other signal sequences) remains an elusive problem. In this regard, recent research suggests that signals other than those at the splice sites play a role in the definition of the intron boundaries. Computational analysis have revealed enhancer sequences that promote splicing of introns with constitutively weak sites, as well as repressor sequences that would prevent splicing of "pseudoexons" with otherwise strong splice signals. See Article 24, **Exonic splicing enhancers and exonic splicing silencers**, Volume 7 for a more in-depth review of exonic splicing enhancers.

3. Prediction of coding regions

Protein-coding regions exhibit characteristic DNA sequence composition bias, which is absent for noncoding regions (Figure 2). The bias is a consequence of (1) the uneven usage of the amino acids in real proteins, (2) the uneven usage of synonymous codons, and (3) dependencies between adjacent amino acid residues in proteins. To discriminate protein coding from noncoding regions, a number of content measures can be computed to detect this bias (see Guigó, 1999). Such content measures – also known as coding statistics – can be defined as functions that compute a real number related to the likelihood that a given DNA sequence codes for a protein (or a fragment of a protein). Since the early eighties, a great number of coding statistics have been published in the literature. Hexamer frequencies usually in the form of fifth-order Markov Models (Borodovsky and McIninch, 1993) appear to offer the maximum discriminative power, and are at the core of most popular gene finders today. Combination of a number of coding statistics, on the other hand, seem to improve performance, as in the pioneer GRAIL program (Uberbacher and Mural, 1991).

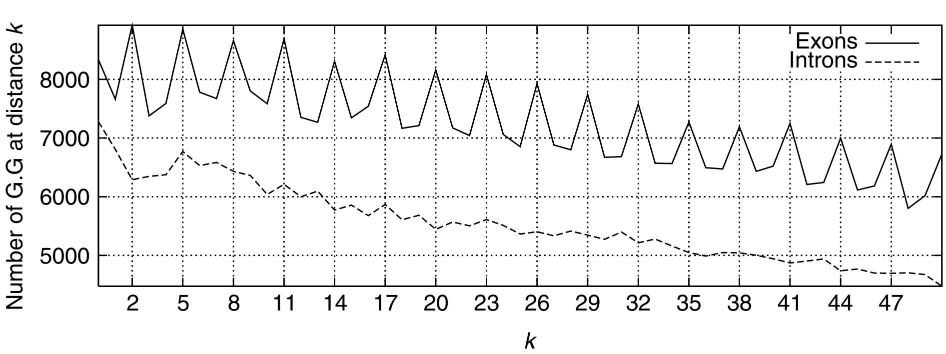

Figure 2 The absolute frequency of the pair G ... G with k (from 0 to 50) nucleotides between the two A's in the 200 first base pairs accumulated in a set of 1753 human exons and introns. A clear period-3 pattern appears in coding regions, which is absent in noncoding regions. This periodic pattern is a reflection of the characteristic codon usage that can be used to distinguish coding from noncoding regions (see Guigó, 1999)

4. "Ab intitio" gene prediction

Most existing computational gene-prediction programs combine at least prediction of sequence signals and prediction of coding regions. Typically, these programs carry out the following tasks: (1) identification of splice sites and other exon-defining sequence signals, (2) prediction of candidate exons based on the predicted signals, (3) scoring of the exons as a function, at least, of the score of the defining signals and the coding statistics computed on the exon sequence, and (4) assembling of a subset of the predicted exons into an "optimal" gene structure – usually the gene structure that maximizes a given scoring function. If this is a linear function of the exon scores, a computational technique known as *dynamic programming* (*see* Article 26, **Dynamic programming for gene finders**, Volume 7) is able to find the solution very efficiently. The programs GENEID (Guigó *et al*., 1992) and FGENESH (Solovyev *et al*., 1995) use this approach explicitly. Under the assumption of linearity in the scoring schema, hidden Markov models (HMMs, *see* Article 98, **Hidden Markov models and neural networks**, Volume 8) offer a robust framework where the optimal structure can also be obtained very efficiently, with the advantage that it has a precise probabilistic interpretation. Since the development of GENSCAN (Burge and Karlin, 1997), a program that has been widely used in the annotation of vertebrate genomes, HMMs have been very popular for gene finding. Pioneer HMM gene finders include GENIE (Kulp *et al*., 1996) and HMM-gene (Krogh, 1997).

5. Homology-based gene prediction

When the query genomic sequence encodes genes with known protein or expressed sequence tag (EST) homologs, this information can be used to improve the predictions. One approach is to incorporate in the exon-scoring schema of an underlying "ab initio" program the quality of the alignment between a putative exon and known coding sequences. GENOMESCAN (Yeh *et al*., 2001), an extension of GENSCAN, among others, incorporates protein similarity, while GRAIL-EXP, an extension of GRAIL, is an early example incorporating similarity to ESTs.

When the homology is very strong (or the genomic sequence encodes a known gene or a gene with ESTs), a more sophisticated approach involves aligning the genomic query directly against the known protein or cDNA target. These alignments, often referred to as "spliced alignments" (*see* Article 15, **Spliced alignment**, Volume 7), are usually computationally expensive and cannot be used for database searches, requiring the target sequence to be known in advance. PROCRUSTES (Gelfand *et al*., 1996) and GENEWISE (Birney and Durbin, 1997) are a few examples of this approach.

6. Comparative gene prediction

Comparative (or dual) genome gene predictors rely on the fact that functional regions in the genome sequence – protein-coding genes in particular – are more

conserved during evolution than nonfunctional ones. Over the last few years, a number of programs have been developed that exploit sequence conservation between two genomes. A wide variety of strategies has been explored, ranging from complex extensions of the classical dynamic programming algorithm for sequence alignment that allow for heterogeneous models of sequence conservation to extensions of single-genome predictors allowing for the integration of sequence conservation with another genome in the exon-scoring schema. Comparative gene predictors outperform their single genome "ab initio" counterparts, and three such predictors, SGP-2 (Parra *et al*., 2003), SLAM (Alexandersson *et al*., 2003), and TWINSCAN (Korf *et al*., 2001) have been used in the comparative annotation of the human and rodent genomes (mouse, rat papers). SLAM is a pair-HMM-based method (*see* Article 17, **Pair hidden Markov models**, Volume 7), in which gene prediction and sequence alignment are obtained simultaneously. TWINSCAN is an extension of GENSCAN, while SGP-2 is an extension of GENEID. The probability scores that these two programs assign to each potential exon are modified by the presence and quality of genome alignments.

As the number of genomes sequenced at different evolutionary distances increases, methods to predict genes on the basis of the analysis of multiple species – and not of two species only – are being investigated. In the so-called phylogenetic hidden Markov models (phylo-HMMs) or evolutionary hidden Markov models (EHMM), a gene-prediction HMM is combined with a set of evolutionary models, thus taking into account that the rate (and type) of evolutionary events differs in protein-coding and noncoding regions. The recent application of phylo-HMMs to gene prediction has produced encouraging results (for instance, Siepel and Haussler, 2004). See Article 27, **Gene structure prediction by genomic sequence alignment**, Volume 7 for a more in-depth review of comparative gene-prediction methods.

7. Gene prediction in complete genomes

While a number of gene-prediction programs are efficient enough that they can be easily run on complete eukaryotic genomes, integrated pipelines that execute a number of analysis programs and weigh the different sources of evidence provide the most accurate gene annotations on complex genomes. Probably, the best-known eukaryotic system is ENSEMBL (**http://www.ensembl.org**, *see* Article 97, **Ensembl and UniProt (Swiss-Prot)**, Volume 8). In the ENSEMBL pipeline, protein-coding database searches and predictions by GENSCAN are used to identify targets for genomic to protein alignments by GENEWISE. The annotation of the *Tetraodon nigroviridis* genome used a different pipeline, based on the GAZE system. GAZE (Howe *et al*., 2002) is a generic framework for the integration of arbitrary gene-prediction data (from sequence signals to complete gene predictions) using dynamic programming. A more in-depth review of gene-finding pipelines can be found elsewhere in this encyclopedia.

Integrated pipelines, complemented with comparative gene-prediction programs, appear to provide accurate enough first-pass annotation of complex eukaryotic genomes when good collections of cDNA or EST sequences exist. Coupled with

recent advances in pseudogene detection methods, they have reached a point where computational predictions can be used as a hypothesis to drive experimental annotation via systematic RT-PCR.

When the collections of expression data are poor or nonexistent, however, computational predictions are less reliable. For instance, experimental cloning of genes initially predicted in *Caenorhabditis elegans* revealed at least 50% of incorrect exonic structures (Reboul *et al*., 2003). The problem is compounded in those cases for which no phylogenetically related genome has been sequenced. The lack of expression data makes it very difficult to estimate the parameters of the gene-prediction programs, and the common practice of using a gene predictor trained on a different, phylogenetically distant species may lead to poor predictions (Korf, 2004). Since a precise assessment of the accuracy of the gene predictions is important, substantial effort has been made during the last decade to develop consistent accuracy metrics and standard datasets. See Guigó and Wiehe (2003) for a review of efforts to evaluate the accuracy of gene-prediction programs.

In summary, while substantial progress has occurred in the field during the last 15 years, computational gene prediction is still an open problem whose solution will require, not only more sophisticated computational methodologies, but a better understanding of the biological mechanisms by which the sequence signals involved in gene specification are processed and recognized in the eukaryotic cell.

Specialist Review

Spliced alignment

Xiaoqiu Huang
Iowa State University, Ames, IA, USA

1. Introduction

Finding genes in genomic DNA sequences is a fundamental step in genome analysis. Spliced alignment is an effective method for finding multiexon genes for which a similar cDNA or protein sequence is available. A cDNA sequence is either of full length or of partial length such as an expressed sequence tag (EST). The coordinates of exons that are similar to a cDNA or protein sequence are located on the basis of sequence similarity and splice site strength. This approach is very accurate if exons are highly similar to a cDNA or protein sequence.

In this chapter, we first present a mathematical formulation of the spliced alignment problem such that a mathematically optimal solution is likely to be exactly correct in exon coordinates. Both sequence similarity and splice site strength are included in the formulation. Then, we describe a dynamic programming algorithm for computing an optimal spliced alignment of a genomic sequence and a cDNA sequence. We briefly discuss spliced alignment methods that explore protein sequence similarity. Next, we present a fast method for dealing with a large set of genomic sequences and a set of cDNA sequences. We also describe methods used in existing spliced alignment programs and comment on their strengths. Finally, we offer suggestions for future improvements in spliced alignment.

2. An alignment model

A similarity relationship between a genomic sequence A and a cDNA sequence B is represented by an alignment of the two sequences, an ordered list of pairs of letters of A and B. The alignment consists of substitutions, deletion gaps, and insertion gaps. A substitution pairs a letter of A with a letter of B. A substitution is a match if the two letters are identical and a mismatch otherwise. A deletion gap is a gap in which letters of A correspond to no letter of B, and an insertion gap is a gap in which letters of B correspond to no letter of A. The length of a gap is the number of letters involved. Deletion and insertion gaps are defined with regard to transformation of sequence A into sequence B. An alignment of A and B shows a way to transform A into B, where a letter of A is replaced by a letter of B in every

```

Figure 1 An alignment of a genomic DNA sequence and a cDNA sequence. A match is indicated by a vertical bar, a mismatch is indicated by a blank, each intron deletion gap is indicated by a number of plus symbols, and other gaps are indicated by a number of dash symbols. This alignment contains 24 matches, 1 mismatch, an exon deletion gap of length 2, an insertion gap of length 1, and three intron deletion gaps of lengths 7, 16, and 11

substitution, the letters of A in every deletion gap are deleted, and the letters of B in every insertion gap are inserted.

There are two types of deletions gaps: exon deletion gaps and intron deletion gaps. Exon deletion gaps are introduced to represent minor differences between exon regions of A and regions of B, whereas intron deletion gaps are intended to represent major differences involving introns and other regions of A that do not correspond to any part of B. An alignment of a genomic DNA sequence and a cDNA sequence is shown in Figure 1.

The similarity of an alignment is measured by a numerical score. Let $\sigma(a,b)$ be the score of a substitution involving letters a and b. Let numbers q and r be gap-open and gap-extension penalties respectively. The numbers q and r are nonnegative. The score of an insertion or exon deletion gap of length h is $-(q + h \times r)$. Let k be a minimum cutoff on the lengths of intron deletion gaps. Let $d = q + k \times r$ be the penalty for a gap of length k. Let $do(i)$ denote the prediction score of a candidate donor site starting at position i of A, where position $i - 1$ belongs to a candidate exon region and position i belongs to a candidate intron region. Let $ac(i)$ denote the prediction score of a candidate acceptor site ending at position i of A, where position i belongs to a candidate intron region and position $i + 1$ belongs to a candidate exon region. The score of an intron deletion gap involving a region from positions i_s to i_e of A is $do(i_s) - d + ac(i_e)$. The similarity score of an alignment is just the sum of scores of each substitution and each gap in the alignment.

Values for the parameters σ, k, q, and r are specified by the user. A letter-independent substitution table is usually used for comparison of DNA and cDNA sequences. For example, each match is given a score of 10 and each mismatch a score of −20. Possible values for q and r are 40 and 2 respectively. For candidate donor sites with the GT dinucleotide and candidate acceptor sites with the AG dinucleotide, which are called canonical splice sites, their prediction scores are obtained by using a statistical method (Zhang and Marr, 1993; Salzberg, 1997; Brendel and Kleffe, 1998) and scaling resulting scores to a range from $-c \times r$ to $c \times r$, where c is a positive integer constant. For the remaining candidate donor and acceptor sites, their prediction scores are $-c \times r$. For example, a value of 5 is used for both c and k, each canonical candidate site is given a score of 10, and each noncanonical candidate site is given a score of −10. The score of the alignment in Figure 1 is −36 under the parameter values given above.

An optimal spliced alignment of two sequences A and B is an alignment of A and B with the maximum score. In the optimal alignment, exon regions of A are likely to be aligned with regions of B, and long introns and intergenic regions of A are likely to be treated as intron deletion gaps because intron deletions gaps are given a constant penalty. Exon–intron boundaries in A are likely to be exactly shown on the optimal alignment because the prediction scores of donor and acceptor sites are used in the definition of the optimal alignment.

3. A dynamic programming algorithm

Let $A = a_1\ a_2\ \ldots\ \ a_m$ be a genomic DNA sequence of length m and $B = b_1\ b_2\ \ldots\ \ b_n$ be a cDNA sequence of length n. A dynamic programming algorithm is developed to compute an optimal spliced alignment of A and B. Let $A_i = a_1\ a_2\ \ldots\ \ a_i$ and $B_j = b_1\ b_2\ \ldots\ \ b_j$ be the initial segments of lengths i and j of A and B. In the algorithm, a matrix S is introduced: $S(i,j)$ is the maximum score of all alignments of A_i and B_j. Thus, $S(m,n)$ is the score of an optimal spliced alignment of A and B. To compute the matrix S efficiently for $i > 0$ and $j > 0$, partition the set of all alignments of A_i and B_j into four groups. Group 1 consists of alignments of A_i and B_j ending with a substitution. Group 2 consists of alignments of A_i and B_j ending with an exon deletion gap. Group 3 consists of alignments of A_i and B_j ending with an insertion gap. Group 4 consists of alignments of A_i and B_j ending with an intron deletion gap.

Three additional matrices ED, ID, and I are introduced for groups 2 through 4. Define $ED(i,j)$ (ED for exon deletion) to be the maximum score of alignments in group 2. Define $I(i,j)$ (I for insertion) to be the maximum score of alignments in group 3. Define $ID(i,j) + ac(i)$ (ID for intron deletion) to be the maximum score of alignments in group 4. Note that the score of each alignment in group 4 includes the term $ac(i)$ as part of the score of an intron deletion gap ending at position i. A partial score of an alignment in group 4 is the score of the alignment minus $ac(i)$. Thus, $ID(i,j)$ is the maximum partial score of alignments in group 4. The introduction of the partial score leads to a simple formula for computing $ID(i,j)$.

On the basis of the definitions of the matrices given above, the recurrences for computing the matrices S, ED, I, and ID can be developed. The correctness proof for the recurrences is omitted. The complete recurrences for the matrices are given below.

$$
\begin{aligned}
S(0,0) &= 0 \\
S(i,0) &= \max\{ED(i,0), ID(i,0) + ac(i)\} \text{ for } i > 0 \\
S(0,j) &= I(0,j) \text{ for } j > 0 \\
S(i,j) &= \max\{S(i-1,j-1) + \sigma(a_i,b_j), ED(i,j), I(i,j), \\
&\qquad ID(i,j) + ac(i)\} \text{ for } i > 0 \text{ and } j > 0 \qquad (1)
\end{aligned}
$$

$$ED(0, j) = S(0, j) - q \text{ for } j \geq 0$$
$$ED(i, 0) = ED(i-1, 0) - r \text{ for } i > 0$$
$$ED(i, j) = \max\{ED(i-1, j) - r, S(i-1, j) - q - r\}$$
$$\text{for } i > 0 \text{ and } j > 0 \qquad (2)$$

$$I(i, 0) = S(i, 0) - q \text{ for } i \geq 0$$
$$I(0, j) = I(0, j-1) - r \text{ for } j > 0$$
$$I(i, j) = \max\{I(i, j-1) - r, S(i, j-1) - q - r\}$$
$$\text{for } i > 0 \text{ and } j > 0 \qquad (3)$$

$$ID(0, j) = S(0, j) + do(1) - d \text{ for } j \geq 0$$
$$ID(i, 0) = ID(i-1, 0) \text{ for } i > 0$$
$$ID(i, j) = \max\{ID(i-1, j), S(i-1, j) + do(i) - d\}$$
$$\text{for } i > 0 \text{ and } j > 0 \qquad (4)$$

The matrices can be computed in order of rows or columns. The value $S(m,n)$ is the score of an optimal spliced alignment of A and B. If only the score $S(m,n)$ is needed, then three linear arrays and a few scalars are sufficient to carry out the computation. This algorithm is an extension to standard global alignment algorithms (Needleman and Wunsch, 1970; Sellers, 1974; Wagner and Fischer, 1974; Waterman *et al*., 1976; Gotoh, 1982).

An optimal alignment is found by a traceback procedure through the matrices S, ED, I, and ID. The aligned pairs of an optimal alignment are generated in a reverse order with the last aligned pair produced first. The traceback procedure is based on the following observations. Let $R(A_m, B_n)$ denote an optimal alignment of A and B. If $S(m, n) = S(m-1, n-1) + \sigma(a_m, b_n)$, then the last aligned pair of $R(A_m, B_n)$ is a substitution pair. Otherwise, if $S(m, n) = ED(m, n)$, then thelast aligned pair is an exon deletion pair. Otherwise, if $S(m, n) = I(m, n)$, then the last aligned pair is an insertion pair. Otherwise, we have $S(m, n) = ID(m, n)$, and the last aligned pair is an intron deletion pair. Next, the procedure is repeated to produce the aligned pairs of the portion of $R(A_m, B_n)$ before the last pair.

Specifically, the traceback procedure consists of four cases, one for each matrix. Initially, the current entry is (m,n) in S. First, consider the case in which the current entry is (i,j) in S. If $i = 0$ and $j = 0$, then the traceback procedure terminates. Otherwise, if $i > 0$ and $S(i, j) = ED(i, j)$, then the current entry becomes (i,j) in ED. Otherwise, if $j > 0$ and $S(i, j) = I(i, j)$, then the current entry becomes (i,j) in I. Otherwise, if $i > 0$ and $S(i, j) = ID(i, j)$, then the current entry becomes (i,j) in ID. Otherwise, the current entry becomes $(i-1, j-1)$ in S and a substitution pair (a_i, b_j) is reported.

Then, consider the case in which the current entry is (i,j) in ED. An exon deletion pair $(a_i, -)$ is reported. If $i > 1$ and $ED(i, j) = ED(i-1, j) - r$, then the current entry becomes $(i-1,j)$ in ED. Otherwise, the current entry becomes $(i-1,j)$ in S.

Next, consider the case in which the current entry is (i,j) in I. An insertion pair $(-, b_j)$ is reported. If $j > 1$ and $I(i, j) = I(i, j-1) - r$, then the current entry becomes $(i,j-1)$ in I. Otherwise, the current entry becomes $(i,j-1)$ in S.

Finally, consider the case in which the current entry is (i,j) in ID. An intron deletion pair $(a_i, -)$ is reported. If $i > 1$ and $ID(i, j) = ID(i-1, j)$, then the current entry becomes $(i-1,j)$ in ID. Otherwise, the current entry becomes $(i-1,j)$ in S.

The traceback procedure requires that the complete matrices be saved or additional information be saved to indicate how the value at each matrix entry is generated, which takes computer memory proportional to the product $m \times n$. For example, on a genomic sequence of 100 000 bp and a cDNA sequence of 1000 bp, the algorithm requires about 100–400 MB of memory. The time requirement of the algorithm is also proportional to the product $m \times n$. For example, the algorithm requires less than 1 min on an ordinary computer to produce an optimal alignment of a genomic sequence of 100 000 bp and a cDNA sequence of 1000 bp. The space requirement of this algorithm is much more limiting than the time requirement.

An optimal alignment of a genomic sequence and a cDNA sequence can be computed in computer memory proportional to the sum of the sequence lengths by a divide-conquer technique (Hirschberg, 1975; Myers and Miller, 1988). The main idea of this technique is to determine a middle pair of positions on an optimal alignment in linear space. Then, the portions of the optimal alignment before and after the middle pair of positions are constructed recursively. This space-efficient technique is used in several programs for computing spliced alignments (Mott, 1997; Huang *et al*., 1997; Usuka *et al*., 2000).

We would like to point out that a dynamic programming algorithm could be developed for a version of the spliced alignment problem based on protein sequence similarity. The algorithm is able to produce, in presence of frameshifts, a strongest similarity relationship between codons of a genomic sequence and amino acids of a protein sequence. There are a few existing spliced alignment programs based on protein sequence similarity (Gelfand *et al*., 1996; Huang and Zhang, 1996; Usuka and Brendel, 2000).

4. Fast comparison of genomic and cDNA sequences

A general strategy for comparing a large set of genomic sequences with a set of cDNA sequences proceeds in two steps. In step 1, short word matches between genomic and cDNA sequences are quickly located through a lookup table (Pearson and Lipman, 1988; Altschul *et al*., 1990). Each word match is extended into a high-scoring segment pair (HSP), an ungapped alignment. Then, HSPs from the same pair of genomic and cDNA sequences are combined into chains (Wilbur and Lipman, 1983; Chao and Miller, 1995; Huang, 1996), where a chain of HSPs is an approximation to an alignment, with each HSP being an ungapped portion of the

alignment. In step 2, for each high-scoring chain between a region of a genomic sequence and a cDNA sequence, a small area of the dynamic programming matrix is located to cover all the HSPs in the chain. Then, a largest-scoring alignment of the genomic region and the cDNA sequence is produced by restricting the dynamic programming computation to the area.

Variations of this general strategy are used in the following programs: est2genome (Mott, 1997), DDS/GAP2 (Huang *et al*., 1997), sim4 (Florea *et al*., 1998), GeneSeqer (Usuka *et al*., 2000), Spidey (Wheelan *et al*., 2001), and BLAT (Kent, 2002).

The est2genome program works in three steps. In step 1, a genomic sequence is compared with a set of cDNA sequences with BLAST (Altschul *et al*., 1990). For each cDNA sequence similar to the genomic sequence, the start and end positions of an optimal local alignment are computed by the Smith–Waterman algorithm (Smith and Waterman, 1981). Then, the corresponding regions of the genomic and cDNA sequences are extracted and an optimal alignment of the two regions is computed by a dynamic programming algorithm in linear space. The GT-AG dinucleotides are used to locate splice sites. The est2genome program is good at computing cross-species alignments.

The DDS program identifies regions of the genomic sequence that are similar to a cDNA sequence in the database, on the basis of step 1 of the general strategy described above. The GAP2 program computes an alignment for each pair of genomic region and cDNA sequence by using a linear-space dynamic programming algorithm based on the GT-AG dinucleotides. The DDS/GAP2 program is suitable for computing cross-species alignments.

The sim4 program works in four steps. In step 1, perfect word matches of length 12 between genomic and cDNA sequences are extended into HSPs. In step 2, HSPs are combined into chains. Each exon core is represented by a set of close HSPs. In step 3, the boundaries of exon regions in the genomic and cDNA sequences are determined by a speedy method based on sequence similarity and the GT-AG dinucleotides. In step 4, for each pair of exon regions of the genomic and cDNA sequences, an alignment of the exon regions is produced by a fast method (Chao *et al*., 1997). A main strength of sim4 is its ability to perform cross-species comparisons at a great speed.

In the GeneSeqer program, pairs of similar genomic regions and cDNA sequences are found by extending word matches of length 12 into HSPs and combining HSPs into chains. Then, for each pair of similar genomic region and cDNA sequence, an optimal alignment is computed by scoring for both sequence similarity and potential splice site strength. The strengths of splice sites are scored by using a statistical method (Brendel and Kleffe, 1998) instead of the GT-AG dinucleotides. A main strength of GeneSeqer is its ability to find short exons on the basis of their splice site strength.

The Spidey program finds exon–intron boundaries in a genomic sequence by repeatedly performing fast searches with BLAST. Initially, HSPs between the genomic sequence and cDNA sequences are computed by BLAST at a high stringency ($e = 10^{-6}$). Then, regions of the genomic sequence are located such that all HSPs in a region are nonoverlapping and linearly consistent. Next, for each genomic region, HSPs between the genomic region and the cDNA sequence are computed

by BLAST at a lower stringency ($e = 10^{-3}$). For each gap between HSPs, additional HSPs are computed by BLAST at a low stringency ($e = 1$). Close HSPs are merged into alignments such that each alignment corresponds to one exon. Finally, potential splice sites around the ends of the alignments are scored and selected. A main strength of Spidey is that its performance is not affected by wide variations in intron size.

In the BLAT program, a lookup table is constructed for all nonoverlapping words of length k in the set of genomic sequences, where k is an integer between 8 and 16. Then, the set of cDNA sequences is scanned to locate perfect or near perfect word matches between genomic and cDNA sequences. If there are a sufficient number of word matches between a genomic sequence and a cDNA sequence, then those word matches are extended into HSPs. Close HSPs are linked together into an alignment by using a fast method based on sequence similarity and the GT-AG dinucleotides. BLAT is also able to speed up the comparison by using many processors. A main strength of BLAT is its ability to handle huge sets of genomic and cDNA sequences from the same species.

Four existing programs, DDS/GAP2, est2genome, sim4, and GeneSeqer, were used and compared by Haas *et al*. (2002) in a rigorous reannotation effort to map 5016 full-length cDNA sequences from *Arabidopsis* to its genome. The four programs produced identical splice sites for 4918 of the 5016 cDNA sequences; the programs disagreed on less than 2% of the cDNA sequences. However, the programs are different in their strengths. DDS/GAP2 is better at matching the entire cDNA to the genome than any of the other programs. GeneSeqer is excellent at finding short exons of 3–25 bp. SIM4 is much faster than any of the other programs.

5. Future developments

We suggest three issues for future studies: identification of short exons, construction of a weight array matrix for noncanonical splice sites, and comparison of cross-species sequences. Short exons are difficult to find because short exon matches are much less significant than long exon matches in assessment of exons. This issue may be addressed through development of a special method to put more weight on splice site strength. As more noncanonical splice sites are known, it may be possible to construct a weight array matrix for noncanonical splice sites. If the matrix is useful for finding noncanonical splice sites, then the matrix can be incorporated in existing alignment algorithms. The full matrix versions of dynamic programming algorithms are sensitive in computing cross-species alignments but are very slow for large-scale applications. It may be possible to improve the efficiency of those algorithms without a significant loss in sensitivity.

Specialist Review

Searching for genes and biologically related signals in DNA sequences

Mihaela Pertea
The Institute for Genomic Research, Rockville, MD, USA

1. Introduction

Complex software systems integrating sophisticated machine learning techniques have been developed to elucidate the structures and functions of genes, but accurate gene annotation is still difficult to achieve, primarily due to the complexity inherent in biological systems. If the biological signals surrounding coding exons could be detected perfectly, then the protein-coding regions of all genes could be identified simply by removing the introns, concatenating all the exons, and reading off the protein sequence from start to stop. Not surprisingly, most successful gene-finding algorithms integrate signal sensors that are intended to identify the usually short sequence patterns in the genomic DNA that correspond directly to regions on mRNA or pre-mRNA that have an important role in splicing or translation. Unfortunately, DNA sequence signals have low information content and are very hard to distinguish from nonfunctional patterns, making signal detection a challenging classification problem.

This review provides mainly background information about signal prediction in the gene-finding framework from a computational perspective, without giving too many biological details (for which the interested reader is invited to look at the cited papers). It starts by presenting the most frequently predicted biological signals and ends with a general overview of the most widely used methods in signal detection.

2. Commonly predicted biological signals

The signals that are usually modeled by gene-finding packages are transcription promoter elements, translational start and stop codons, splice sites, and polyadenylation sites, but computational methods have been designed for many other signals, including branch points, ribosome-binding sites, transcription terminators, exon enhancers, and various transcription factor binding sites. In this section, we present some of the biological signals that are most often addressed by signal recognition programs. These signals are shown in Figure 1 in rapport to the structure of a gene.

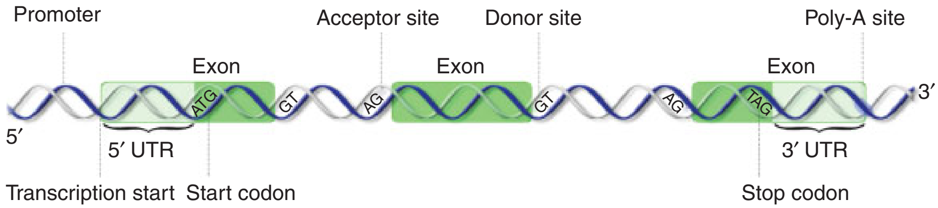

Figure 1 Important biological signals usually modeled by gene finders

2.1. Splice sites

Splice sites are one class of signals that determine the boundaries between exons and introns. The biological rules that govern splice site selection are not completely understood (Reed, 2000). It is well known, though, that recognition of the splicing signals in pre-mRNA is carried out by a complex of proteins and small nuclear RNAs known collectively as the spliceosome, which splices out the introns and produces the mature mRNA transcript. The components of the spliceosome are, in general, highly conserved among eukaryotes (Mount and Salz, 2000), but the splice site consensus sequences are short and degenerate. Usually, the 5′ boundary or donor site of introns in most eukaryotes contains the dinucleotide GT (GU in pre-mRNA), while the 3′ boundary or acceptor site contains the dinucleotide AG. In addition to these dimers, a pyrimidine-rich region precedes the AG at the acceptor site, a shorter consensus follows the GT at the donor site, and a very weak consensus sequence appears at the branch point, approximately 30 nucleotides (nt) upstream from the acceptor site.

A number of computational methods have been developed to identify splice sites. Some are stand-alone splice site finders (see for instance Hebsgaard *et al*., 1996; Reese *et al*., 1997; Brendel and Kleffe, 1998; Pertea *et al*., 2001 for a few examples), but often gene finders identify splice sites as a subroutine, and their performance is greatly influenced by the quality of these splice sensors.

2.2. Translational start and stop codons

Since translational start and stop codons, together with the splice sites, determine the complete coding portion of a gene, their recognition is crucial to the success of computational gene-finding strategies. Unfortunately, patterns in the vicinity of the translational start and stop sites are even less distinctive than those around the splice sites. While the translational stop is almost always identified by the first in-frame stop codon, computational recognition of the start codon proves to be a difficult task in gene finding. Shine-Dalgarno (Shine and Dalgarno, 1974) and Kozak sequences (Kozak, 2001) describe consensus motifs in the context of the translation initiation both in bacteria and in eukaryotes. However, these consensus patterns have very limited power in discriminating the true start codons from other potential starts in a DNA sequence. The lack of strong identifying signals means

that start signal recognition usually has very high false-positive rates, even higher than in the case of splice site detection (Salzberg, 1997; Pertea and Salzberg, 2002).

2.3. Promoters and transcription start sites

Finding the DNA site to which RNA polymerase will bind and initiate transcription is such a complicated task that most gene finders do not even attempt to integrate it into the prediction model. A gene recognition program will usually predict only the protein coding region of the gene, from start to stop codon, leaving the untranslated exons and exon segments to be discovered by other methods. These methods frequently focus on the discovery of the transcription start site (TSS) of a gene, by trying to identify the promoter region, which is usually located adjacent to the TSS.

The promoter region typically extends 150–300 bp upstream from the transcription start site (in prokaryotes), and contains binding sites for RNA polymerase and a number of proteins that regulate the rate of transcription of the adjacent gene. Most bacterial promoters contain the consensus sequences TATAAT and TTGACA at around 10 bp and 35 bp respectively upstream of the TSS (Galas *et al*., 1985). Much less is known about eukaryote promoters. Most computational methods try to recognize the Goldberg–Hogness or TATA box that is centered around 25 bp upstream of the TSS and has the consensus sequence TATAAAA. A CAAT box and a GC-rich element have also been identified in several promoters (Bucher, 1990). Although many promoter and TSS prediction programs have been developed, their performance is less than satisfactory, due to the large numbers of false-positives that are generated (see for instance Fickett and Hatzigeorgiou, 1997; Ohler and Niemann, 2001 for an assessment of recent promoter recognition programs).

2.4. Transcription terminators and polyadenylation sites

At the end of the coding sequences, a signal called the transcription terminator causes the RNA polymerase to slow down and fall off the nascent transcript. It is composed of a sequence that is rich in the bases G and C, and can form a hairpin loop. Prediction of transcription terminators has been achieved with some success in bacterial genomes. Specificity in the 89–98% range was obtained by TransTerm (Ermolaeva *et al*., 2000), which identifies terminators by searching for a hairpin structure in proximity of a downstream U-rich region.

As transcription is nearly completed, a polyadenylation signal where the mRNA is cut is encountered. A polyadenylic acid sequence of varying length is then added posttranscriptionally to the primary transcript as part of the nuclear processing of RNA. This poly-A tail is thought to help transport the mRNA out of the nucleus, and may stabilize the mRNA against degradation in the cytoplasm. Prediction of the location of the poly-A signal is included in many gene-recognition programs, since careful determination of the gene's ends plays an important role in determining the accuracy of the programs. When the end of a gene is not correctly predicted, it tends to be either truncated or fused with the next gene by the gene finder. Poly-A signal prediction has been also considered by stand-alone programs (Salamov

and Solovyev, 1997; Tabaska and Zhang, 1999) that can predict the well-known AAUAAA signal as well as other poly-A sites.

3. Computational methods for signal prediction

In this section, we describe several of the most popular methods for signal detection in DNA sequences, but many others have appeared over the years. These methods range from very simple ones, such as computation of consensus sequences and position weight matrices, to more complex computational methods such as neural networks, Markov models, and decision trees. In general, the best current methods combine many different types of evidence (Salzberg *et al*., 1998), using nucleotides in a relatively wide window around the core sequence pattern. Because all of these methods are essentially statistical, they have become more effective recently, due not to changes in the algorithms but rather to significant increases in the amount of genomic sequence data available.

3.1. Consensus analysis

Consensus sequence methods use a multiple alignment of functionally related sequences to identify the consensus, defined as a composite subsequence created using the most common base at each position in the multiple alignment. New sites are identified simply by matching them to the consensus sequence. The match can be exact or it can be within a neighborhood consisting of all subsequences within a fixed distance k from the consensus sequence, where the most common distance used between two sequences of the same length is the Hamming distance. These techniques have been used to characterize a variety of different biological signals; for example, the consensus (A,C)AG/GU(A,G)AGU with mismatches was described at the 5′ end of introns back in 1990 (Senapathy *et al*., 1990). Different programs implement this technique either by itself or combined with other methods to predict functional sites (e.g., SpliceView (Rogozin and Milanesi, 1997) or SplicePredictor (Brendel and Kleffe, 1998)).

3.2. Weight matrices

The weight matrix model (WMM) summarizes the consensus sequence information by specifying the probabilities of each of the four nucleotides in each position of the DNA sequence (Stormo, 1990; Gelfand, 1995). Values in the weight matrix are determined by aligning known sequences for a given signal type, and computing the fraction of each residue at each position. Formally, if the signal pattern is ℓ nucleotides in length, then the probability that the sequence $X = x_1x_2 \ldots x_\ell$ is a signal of that type is given by $p(X) = \prod_{i=1}^{\ell} p^{(i)}(x_i)$, where $p^{(i)}(x_i)$ is the probability of generating nucleotide x_i at position i of the signal. Fickett (1996) describes a common variation of the above technique, the position weight matrix, which uses the relative frequency of each base in each position by

replacing $p^{(i)}(x_i)$ with $p^{(i)}(x_i)/p(x_i)$, where $p(x_i)$ is the probability of generating nucleotide x_i independent of its position in the signal. An important limitation of the weight matrices is the underlying simplifying assumption of independence between positions. A modified form of the WMM known as "inhomogeneous Markov model" or "weight array model" (IMM/WAM) has been introduced to capture nonindependence between positions (Zhang and Marr, 1993). Most commonly used is the first-order WAM in which the distribution at position i depends on the residue at position $i - 1$, but higher-order WAMs have been also described. While such higher-order models might succeed in reducing the high false-positive rates, they require the estimation of a very large number of parameters, thus an increased amount of training data, which is often not available. To reduce the problem of sample-size limitation, Burge and Karlin (1997) implement a generalization of the WAM, called "windowed weight array model" (WWAM), to detect splice site signals. In this method, the transition probabilities at a given position i are estimated by averaging the conditional probabilities observed at position i with those observed in a neighboring window of positions centered at position i. For instance, a second-order WWAM will estimate the transition probabilities for positions i from the data at positions $i-2, i-1, i, i+1$, and $i+2$, the underlying assumption here being that nearby positions have similar triplet biases.

3.3. Decision trees

A decision tree is a supervised learning method that learns to classify objects from a set of examples (where an "object" can be a DNA sequence or partial sequence). It takes the form of a tree structure of nodes and edges in which the root and the internal nodes test on one of the objects' attributes. Each edge extending from an internal node of the tree represents one of the possible alternatives or courses of action available at that point. Depending on the outcome of the test, different paths in the tree are followed down to the tree's leaves, which carry the names of classes into which the objects are placed. Most decision tree learning systems use an information-theoretic approach that minimizes the number of tests to classify an object. A typical approach is to use an information-based heuristic that selects the attribute providing the highest information gain (Quinlan, 1986), that is, the attribute that minimizes the information needed in the resulting subtrees to classify the elements. Formally, the information gain uses $I = \sum (p_i \ln p_i)$, where p_i is the probability that an object is in class i, as evaluation function for measuring the information of the initial set and the subsets produced after splitting. There have been many other approaches based on different evaluation functions, including the Gini index, chi-square tests, and other metrics (Murthy *et al*., 1994).

Decision tree–based classification methods have applications in a wide variety of domains, including DNA sequence analysis. SpliceProximalCheck (Thanaraj and Robinson, 2000), for example, is a program that uses a decision tree to discriminate true splice sites from false ones that may be located physically close to real ones.

An interesting application of decision trees was introduced by (Burge and Karlin (1997) to model complex dependencies in signals. Their approach, called maximal dependence decomposition (MDD), tries to capture the most significant adjacent

and nonadjacent dependencies in a signal using an iterative subdivision of the training data. MDD trees are constructed from a set D of N aligned DNA sequences of length k, extracted from a set of signal sites. For each of the k positions, let the most frequent base at that position be the consensus base. The variable C_i will be 1 if the nucleotide at position i matches the consensus at position i, 0 otherwise. Next, compute the χ^2 statistics between the variables C_i and X_j (which identifies the nucleotide at position j), for each i, j pair with $i \neq j$. If strong dependencies are detected, then proceed as in Burge and Karlin (1997) by partitioning the data into two subsets based on those positions. Recursive application of this procedure builds a small tree. Each leaf of this tree contains a subset of the signal sites used for training.

3.4. Markov models

Markov models have been in use for decades as a way of modeling sequences of events, and they translate very naturally to DNA sequence data. To score a sequence using a Markov chain, a gene finder needs to compute a set of probabilities from training data. These probabilities take the form $P(b_i|b_{i-1}, b_{i-2}, \ldots)$, where b_i indicates the base in position i of the DNA sequence. Models that use Markov chains rely on the *Markov assumption*, which states that any event x is dependent only on a fixed number of prior events. Clearly, this assumption is not true for all DNA sequences, and the extent to which the Markov assumption is false defines a limitation on the model. Markov chains combined with the MDD method are implemented by the splice site predictor program GeneSplicer (Pertea *et al*., 2001).

Many gene finders such as Genscan (Burge and Karlin, 1997) or GeneMark. HMM (Lukashin and Borodovsky, 1998) model signals (e.g., promoters, poly-A sites, and different enhancers) by using hidden Markov models (HMMs) or their extended form, generalized hidden Markov models (GHMMs). HMMs are Markov chains in which the states are not directly observable, and only the output of a state is observable. HMMs are generally far more complex than Markov chains, because the model need not be a chain; rather, it can contain elaborate loops and branching structures. The output from (or input to) each state is a symbol (or a string of symbols in the case of GHMMs) from a finite set of symbols and is chosen randomly according to some probability distribution over the alphabet of the output symbols. The parameters of the HMM are estimated using an algorithm called the Expectation Maximization (E-M) algorithm, and the most probable interpretation of a DNA sequence is then found with the Viterbi algorithm (Eddy, 1996).

3.5. Neural networks

Neural networks (NNs) are a powerful tool for pattern classification. Some NNs are models of biological neural networks while others are not, but historically, much of the inspiration for the field of NNs came from the desire to produce artificial systems capable of sophisticated computations similar to those that the human brain

routinely performs. There is no room here to review the extensive and complex literature on neural nets, but generally speaking, NNs are networks of many simple processors, each possibly having a small amount of local memory. These networks are usually connected in a layered, feed-forward architecture and have some sort of training rule whereby the weights of connections are adjusted on the basis of data.

Many types of biological signals have been predicted using NNs, including the following: Promoter 2.0 (Knudsen, 1999) and NNPP (Reese, 2001) for promoter prediction, NNSPLICE (Reese *et al*., 1997) and NetGene2 (Hebsgaard *et al*., 1996) for splice site recognition, and NetStart (Pedersen and Nielsen, 1997) for start codon determination.

3.6. Linear and quadratic discriminant analysis

In linear discriminate analysis (LDA), the examples to be classified are represented as points in an n-dimensional space defined by features, each of which represents a measurement of some property of the input. The main purpose of LDA is to predict class membership on the basis of a linear combination of the scores of individual features. This can be represented as a multidimensional hyper-plane (a decision surface) whose coefficients are determined by minimizing the prediction error using positive and negative training data sets. In the field of signal detection, LDA is implemented, for instance, in PromH (Solovyev and Shahmuradov, 2003), a promoter prediction program that uses linear discriminant functions that take into account conserved features and nucleotide sequences of promoter regions in pairs of orthologous genes. Quadratic discriminant analysis (QDA) generalizes LDA by finding an optimal quadratic surface instead. The promoter prediction program CorePromoter (Zhang, 1998) uses QDA computed from 5-tuples in the input DNA sequence to predict promoters.

4. Conclusions and future challenges

The accuracy of gene-recognition programs is relatively high (around 90% sensitivity and specificity) when computed merely on the basis of the number of correctly predicted coding nucleotides, but decreases significantly when considering the number of exons or genes predicted correctly. Determining the exact boundaries of a gene's structural elements is highly influenced by the ability to predict correctly the signals surrounding the DNA coding regions.

Prediction of very small exons or shifted open-reading frames could benefit from better recognition of splicing regulatory patterns. Computational determination of alternative splicing of genes can also benefit from a better understanding of the rules that govern splice site selection (Black, 2000). Alternative splicing appears to be most common in vertebrates (e.g., at least 35% of the genes in the human genome have been shown to be alternatively spliced (Croft *et al*., 2000)), but other metazoan organisms and plants also experience a significant number of alternatively spliced genes (Brown and Simpson, 1998), a phenomenon that raises serious challenges for

the current software programs for gene recognition. A dominant role in the regulation of alternative splicing is played by exon splicing enhancers (ESEs), which activate nearby splice sites and promote inclusion of exons in which they reside. ESEs have only recently begun to be included in computational models (Fairbrother *et al*., 2002; Cartegni *et al*., 2003).

Signals upstream and downstream of genes also have an important role in determining the exact locations of genes. Using currently available methods, it is easier to find the 3′ end of a gene than the 5′ end. More effort needs to be devoted to improving detection of the patterns preceding genes. Numerous TSS and promoter databases (Zhu and Zhang, 1999; Hershberg *et al*., 2001; Shahmuradov *et al*., 2003; Schmid *et al*., 2004; Suzuki *et al*., 2004) have been constructed (though their reliability is highly variable), which can help with the determination of the 5′ end of the genes in various organisms. As more complete genomic sequences and extensive experimental data become available, systematic computational and experimental approaches can be further exploited to increase our ability to find genes and regulatory signals in all organisms.

Specialist Review

Pair hidden Markov models

Marina Alexandersson, Nicolas Bray and Lior Pachter
University of California Berkeley, Berkeley, CA, USA

1. Introduction

Many of the early contributions of computer science to biological sequence analysis consisted of the development of algorithms for pairwise sequence alignment, most notably the Needleman–Wunsch algorithm (Needleman and Wunsch, 1970), which was later extended and refined by Smith, Waterman (Waterman and Smith, 1981), and others. It was only 20 years later, when probabilistic models began to be developed for related problems in sequence analysis that it was first suggested that some of the classical algorithms might have a probabilistic interpretation (Bucher and Hofmann, 1996). This observation has led to numerous developments: more rigorous approaches to parameter estimation (Liu *et al*., 1995), novel annotation systems based on combinations of alignment and gene finding models (Alexandersson *et al*., 2003), and Bayesian sampling methods for alignments (Liu *et al*., 1995) to name a few.

The probabilistic interpretation of alignment is based on modeling sequences using *pair hidden Markov models* (PHMMs). Our goal in this chapter is to explain these models, and their connection to hidden Markov models (HMMs) and phylogenetic models of evolution. These models are now widely used in computational biology, and a complete understanding of their foundations is essential to their proper application and for the development of novel more powerful models that will capture the complexities of sequence evolution. The chapter is organized as follows: we begin by explaining evolutionary models for single bases. This is the beginning of a rich theory, and although we avoid exploring the topic in depth, we point out the crucial nonidentifiability property for two taxa models. This property plays a key role in pairwise sequence alignment. Next, we describe HMMs, which capture positional dependence in biological sequences, and are therefore relevant for PHMMs. We then turn to a complete description of PHMMs, which are instances of *Bayesian multinets*. These are graphical models in which the structure of the graph can depend on the assignments to nodes. This distinction places PHMMs in a separate category from standard HMMs. In fact, the term PHMM suggests that PHMMs are close relatives of HMMs, which is misleading; PHMMs are significantly more complex than HMMs. For biologists, the relevance of PHMMs stems from the fact that they can be used to infer alignments of

sequences. The standard alignment algorithms, such as the Needleman–Wunsch algorithm and its variants, can be interpreted as Viterbi algorithms for PHMMs. This is explained in Section 4 in which we also show that PHMMs can be used to sample alignments efficiently. We conclude by describing biologically relevant extensions of PHMMs.

2. What is an alignment?

PHMMs are mainly used to find alignments between pairs of sequences, so we begin by explaining exactly what we mean by *pairwise alignment*.

Definition 1. A pairwise alignment between two sequences σ^1 and σ^2 from a finite alphabet is a sequence on the alphabet H, I, D that has the property that $\#H + \#I = |\sigma^1|$ and $\#H + \#D = |\sigma^2|$. By $\#H$, $\#I$, $\#D$ we mean the number of occurrences of those characters in the alignment string.

An alignment captures the relationship between two sequences that have evolved from a common ancestor via a series of mutations of bases, represented by H that stands for homology, I (insertions), or D (deletions). The alignment string records the events that led to the present day sequences. Alternatively, alignment can be viewed as an *edit* of σ^1 to produce σ^2. That is, we allow characters from σ^1 to be changed or deleted, or new characters to be inserted. An alignment can be thought of, equivalently, as a record of the edits from σ^1 to σ^2. We make this statement precise in the following section.

The main problem in sequence alignment is to identify good alignments that explain the evolutionary history on the basis of parameters for mutation, insertion, and deletion. Mutation mechanisms are accounted for in PHMMs with the use of evolutionary models. An underlying HMM structure is used to model local sequence characteristics, or insertion/deletion structures. The challenging computational task is to find good alignments among the set of all possible alignments. In particular, if $\mathcal{A}_{n,m}$ is the set of all alignments for two strings of length n and m, the number of elements of $\mathcal{A}_{n,m}$ is the Delannoy number

$$D(n, m) = \sum_i \binom{n}{i} \binom{n + m - i}{m - i} \tag{1}$$

This number is exponential in the lengths of the sequences, leading to a nontrivial computational problem in identifying good alignments.

3. Models

3.1. Evolutionary models for two bases

PHMMs capture point mutations, as well as insertions and deletions in biological sequences. We begin by carefully analyzing single base evolutionary models that

are at the core of PHMMs. We restrict ourselves to DNA. Single base mutation is modeled by continuous time Markov chains:

Definition 2. A *rate matrix* (or *Q-matrix*) is a 4×4 matrix $Q = (q_{ij})$ (with rows and columns indexed by the nucleotides) satisfying the properties

$$\begin{aligned} q_{ij} &\geq 0 \quad \text{for} \quad i \neq j \\ \sum_{j \in \{A,C,G,T\}} q_{ij} &= 0 \quad \text{for all} \quad i \in \{A, C, G, T\} \\ q_{ii} &< 0 \quad \text{for all} \quad i \in \{A, C, G, T\} \end{aligned} \tag{2}$$

Rate matrices capture the notion of *instantaneous rate of mutation* and allow us to calculate the *substitution matrices* $P(t)$, giving the probability that a given base will mutate from one nucleotide to another over a given period of time. The entry of $P(t)$ in row i and column j equals the probability that the substitution $i \to \cdots \to j$ occurs in a time interval of length t. We use the notation $P(i, j;t)$ to denote such an entry. Given a rate matrix Q, these probabilities will be governed by a matrix of differential equations whose solution is provided by the following theorem:

Theorem 3. *Let Q be any rate matrix and $P(t) = e^{Qt} = \sum_{i=0}^{\infty} \frac{1}{i!} Q^i t^i$. Then*

1. $P(s + t) = P(s)P(t)$,
2. *$P(t)$ is the unique solution to $P'(t) = P(t) \cdot Q$, $P(0) = \mathbf{1}$ for $t \geq 0$,*
3. *$P(t)$ is the unique solution to $P'(t) = Q \cdot P(t)$, $P(0) = \mathbf{1}$ for $t \geq 0$.*

Furthermore, a matrix Q is a rate matrix if and only if the matrix $P(t) = e^{Qt}$ is a stochastic matrix (nonnegative with row sums equal to one) for every t.

By fixing the entries in a rate matrix and specifying some time t^*, we obtain a matrix $P(t^*)$ that completely specifies the probabilities for observing the four nucleotides after time t^*, starting with each of the nucleotides A, C, G, or T. One key feature of the evolutionary models that we will consider is *reversibility*. In the case in which the background base frequencies are uniform, this property is equivalent to requiring that the substitution matrices are symmetric.

Substitution matrices can be combined along edges of a tree to form a *phylogenetic model*. We consider only the simplest case consisting of an ancestral base r, which after a speciation event mutates into a base a that we observe after time t_1 and a separate base b that we observe after time t_2. If $P(i, j; t_1, t_2) = Pr(a = i, b = j; t_1, t_2)$ is the probability of observing i and j at a and b after times t_1 and t_2 respectively, then we can write the probability

$$P(i, j; t_1, t_2) = \sum_k Pr(r = k)P(i, k; t_1)P(j, k; t_2) = \frac{1}{4} \sum_k P(i, k; t_1)P(j, k; t_2) \tag{3}$$

where, again, we have assumed a uniform distribution at r. If we include the assumption that $P(t)$ is symmetric for all t, then this completely specifies a statistical model that we call the *general reversible model for two taxa*. The key property of reversible models that we will need for PHMMs is the nonidentifiability of the two taxa general reversible model:

Proposition 4. If $t_1 + t_2 = t_3 + t_4$ then $P(i, j; t_1, t_2) = P(i, j; t_3, t_4)$.

Proof: Since $P(t)$ is symmetric for all t, $P(i, j; t) = P(j, i; t)$ for all i and j. Now as above, we have that

$$P(i, j; t_1, t_2) = \frac{1}{4}\sum_k P(i, k; t_1)P(j, k; t_2) = \frac{1}{4}\sum_k P(i, k; t_1)P(k, j; t_2) \qquad (4)$$

However, the right-hand side of equation (4) is just $\frac{1}{4}$ times the (i, j)th entry of the matrix $P(t_1)P(t_2) = P(t_1 + t_2)$. Similarly, we will have that $P(i, j; t_3, t_4)$ will be $\frac{1}{4}$ times the (i, j)th entry of the matrix $P(t_3 + t_4)$. The result now follows from the assumption that $t_1 + t_2 = t_3 + t_4$.

This proposition shows that we arrive at the same distribution on pairs of nucleotides if we set one of our branch lengths to 0, in which case the model describes not two bases evolving from a common ancestor but rather of one base changing directly into the other. This fact lies at the heart of our ability to refer to alignment as the editing of one sequence into the other, rather than as a description of the evolutionary history from a common ancestor.

3.2. *Phylogenetic models for two sequences*

In order to describe the evolution of entire sequences, rather than single bases, we make use of *HMMs*. In this section, we use them to describe an evolutionary model for sequences, which allows for point mutation and dependence between neighboring nucleotides, without allowing for insertion or deletion, a complexity that is added in the next section.

Definition 5. A discrete hidden Markov model consists of n observed states $Y_1, \ldots, Y_n$ taking on l possible values, and n hidden states $X_1, \ldots, X_n$ taking on k possible values. The HMM can be characterized by the following conditional independence statements for $i = 1, \ldots, n$:

$$p(X_i \mid X_1, X_2, \ldots, X_{i-1}) = p(X_i \mid X_{i-1}),$$
$$p(Y_i \mid X_1, \ldots, X_i, Y_1, \ldots, Y_{i-1}) = p(Y_i \mid X_i).$$

We consider the model with uniform initial distribution, where all probabilities $p(X_i|X_{i-1})$ are given by the same $k \times k$ matrix and all probabilities $p(Y_i|X_i)$ are given by the same $l \times k$ matrix.

The relationship of HMMs to the modeling of pairs of sequences that evolved from a common ancestral sequence is as follows: the random variables $Y_1, \ldots,$

Y_n take on $l = 16$ possible values (consisting of all pairs of nucleotides). The hidden random variables $X_1, \ldots, X_n$ take on $k = 4$ possible states corresponding to the four nucleotides A, C, G, T. The hidden values play the role of the ancestral sequence. Fixing the conditional transition and output probabilities in the HMM results in a probability distribution being defined on pairs of sequences. If the output probabilities are constrained to a reversible model, it is clear from the previous discussion that we have described an evolutionary model for sequences that allows for dependence between neighboring nucleotides in the ancestral sequence.

3.3. *Modeling insertion and deletion*

We are now ready to introduce PHMMs, which add insertions and deletions into the model in Section 3.2. Graphically, this model is represented in Figure 1(a). The boxes around the nodes, called *plates*, are used to indicate that the nodes may not be present. The presence of a node is determined by *class nodes*, small circles in the plates that in our case take on the values 0 (node missing) or 1 (node present). The hidden states take on the values H, I_1, I_2 and D_1, D_2. In the H state, an ancestral base is generated, and from it two observed bases. In the D states, an ancestral base is generated but only one observed base. In the I states, no ancestral base is generated, and one observed base is generated.

Alternatively (and equivalently, because of the nonidentifiability discussed in Section 3.1), we can describe a PHMM with the model in figure 1b. In this case, there are three hidden states: H, I and D. In the I state a base is generated in sequence 1, and in the D state a base is generated in sequence 2. In the H state, two bases are generated from a joint distribution (note that the model as drawn technically requires four H states, one for each base, but this is usually omitted in favor of simply writing the joint probability distribution on the observed nodes directly). The model then consists of a distribution on the initial state of the model, $\{\pi_i\}_{i=1}^{k}$, transition probabilities $s_{ij} = Pr(X_{l+1} = j|X_l = i)$, and an output distribution from each state j, $b_j(x, y) = Pr(x, y|X_l = j)$, where x, y range over all possible pairings of bases, allowing for the null base. Note that the fact that the output distribution now includes "null characters" allows for the instances where one or the other observed nodes is not present in the model. For example, $b_I(A, \emptyset)$ is the probability of an A being observed at the first node when the second node is not present in the model.

Given two sequences σ^1 and σ^2 of lengths N and M respectively, this model allows us to assign a probability to any alignment h in $\mathcal{A}_{N,M}$. The alignment h is a sequence of Hs, Is, and Ds and this will be our sequence of hidden states. Adopting the notation of Pachter and Sturmfels (2005), we define $h[i]$ to be $\#H + \#I$ in the prefix $h_1 h_2 \ldots h_i$ of h, and $h\langle i\rangle$ to be $\#H + \#D$ in $h_1 h_2 \ldots h_i$. Thus, $h[i]$ is our position in σ^1 at step i of the alignment and $h\langle i\rangle$ is our position in σ^2. Then the probability of the alignment h according to our model will be

$$\pi_{h_1} b_{h_1}(\sigma^1_{h[1]}, \sigma^2_{h\langle 1\rangle}) \prod_{i=2}^{L} s_{h_{i-1}h_i} b_{h_i}(\sigma^1_{h[i]}, \sigma^2_{h\langle i\rangle}) \tag{5}$$

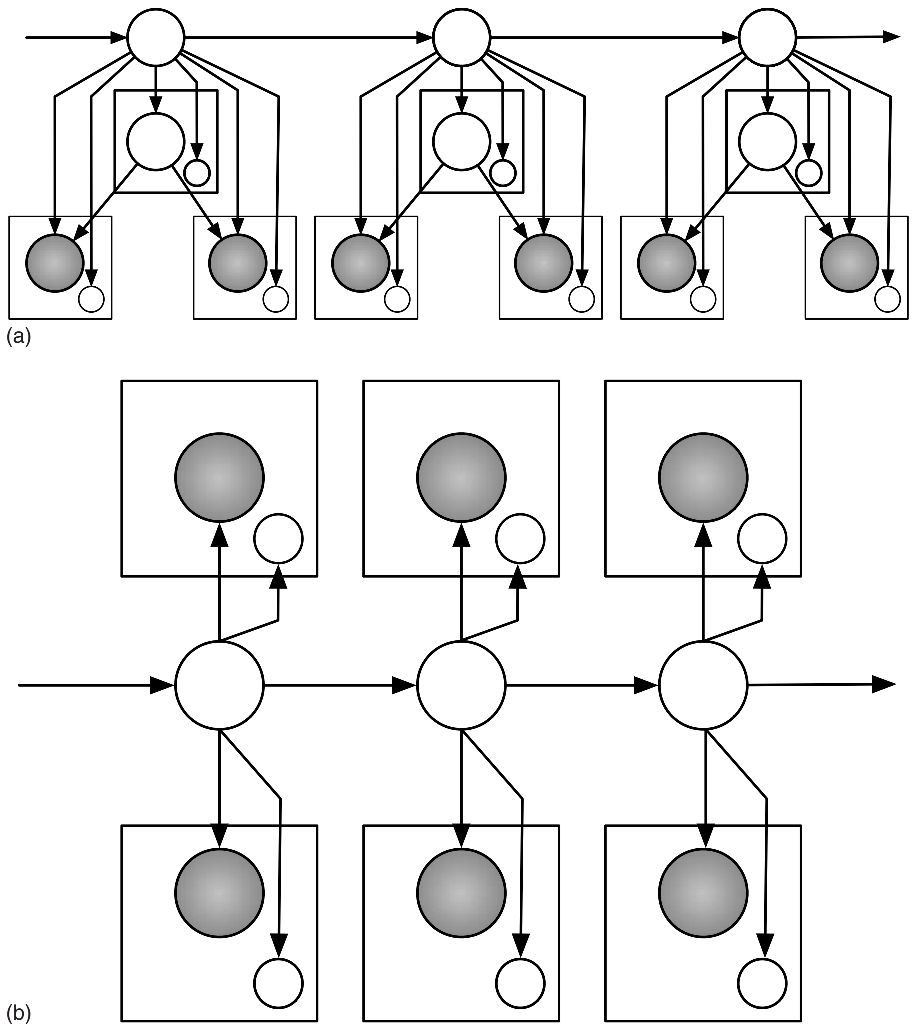

Figure 1 The pair hidden Markov model

From this we can calculate the probability of two sequences:

$$P(\sigma^1, \sigma^2) = \sum_{h \in \mathcal{A}_{N,M}} \pi_{h_1} b_{h_1}(\sigma^1_{h[1]}, \sigma^2_{h\langle 1\rangle}) \prod_{i=2}^{L} s_{h_{i-1}h_i} b_{h_i}(\sigma^1_{h[i]}, \sigma^2_{h\langle i\rangle}) \tag{6}$$

Despite the name, PHMMs are nontrivial modifications of standard HMM models, in that the structure of the models is not fixed. In the graphical model literature, these types of models are referred to as Bayesian multinets (Friedman *et al*., 1997).

4. Algorithms

4.1. Finding a best alignment

The model described in the previous section, for some fixed parameters and fixed observed sequences, provides a probability distribution over alignments. Thus, for a given pair of sequences, one obvious question is: what is the most likely alignment of the two sequences according to the model? Stated formally, the question is to find the *maximum a posteriori* (MAP) alignment. The naive method of answering this question would be to enumerate all possible alignments, calculate the probability of each, and select the one with highest probability. This quickly becomes infeasible as the number of possible alignments of two sequences grows exponentially in their length. However, by exploiting the structure of the model, we can find the optimal alignment in time proportional to the product of the lengths of the sequences using the Viterbi algorithm.

The Viterbi algorithm for PHMMs is related to the Viterbi algorithm for HMMs, which is itself a specific instance of the generalized distributive law for inference in graphical models (Aji and McEliece, 2000). It can also be viewed as an instance of the dynamic programming approach, a general method for exploiting recursive structure in optimization problems. As is typical of dynamic programming methods, the Viterbi algorithm solves what would appear to be a much more difficult problem: instead of finding the optimal alignment for the two given sequences, the optimal alignment is calculated for every pair of prefixes of the sequences. For a sequence σ, let $\sigma\langle i\rangle$ denote the prefix $\sigma_1\sigma_2 \ldots \sigma_i$ and denote the two sequences being compared by σ^1 and σ^2. The key observation of the Viterbi algorithm is that in an alignment of $\sigma^1\langle i\rangle$ and $\sigma^2\langle j\rangle$, the final hidden state must be either H, I, or D and so the alignment decomposes naturally into smaller alignments. This is used to recursively compute a matrix δ where $\delta(i, j, s)$ is the probability of the optimal alignment of $\sigma^1\langle i\rangle$ and $\sigma^2\langle j\rangle$ ending in hidden state s. Having computed this matrix, it is then possible to compute the optimal alignment of the entire sequences.

Formally, let $X_1X_2 \ldots X_L$ be the underlying hidden Markov process assuming values in the state space $S = \{H, I, D\}$, (where $L \le N + M$ is the length of the alignment). The process begins in a state determined by the initial distribution $\{\pi_i\}_{i=1}^{k}$ and evolves through the state space according to the transition probabilities $s_{ij} = Pr(X_{l+1} = j|X_l = i)$. The observed sequences σ^1 and σ^2 are sequences of random steps of the hidden process using some output distribution $b_j(\sigma_n^1, \sigma_m^2) = Pr(\sigma_n^1, \sigma_m^2|X_l = j)$. Moreover, in order for the model to represent a distribution over all possible pairs of sequences and their alignments, we need to introduce two silent states, *Begin* and *End*. We initialize the Viterbi algorithm by

$$\begin{aligned} \delta(1, 1, H) &= \pi_H b_H(\sigma_1^1, \sigma_1^2), \\ \delta(1, 0, I) &= \pi_I b_I(\sigma_1^1, \emptyset), \\ \delta(0, 1, D) &= \pi_D b_D(\emptyset, \sigma_1^2) \end{aligned} \tag{7}$$

and the recursion relations become, for $1 \leq n \leq N$ and $1 \leq m \leq M$,

$$\delta(n, m, H) = \max_j \{\delta(n-1, m-1, j) a_{jH} b_H(\sigma_n^1, \sigma_m^2)\}$$
$$\delta(n, m, I) = \max_j \{\delta(n-1, m, j) a_{jI} b_I(\sigma_n^1, \emptyset)\}$$
$$\delta(n, m, D) = \max_j \{\delta(n, m-1, j) a_{jD} b_D(\emptyset, \sigma^2, m)\} \quad (8)$$

where $\emptyset$ represents a gap and $\delta(n, m, j) = 0$ if $n < 0$ or $m < 0$. The recursion is terminated in the *End* state by $\delta(N+1, M+1, i) = \max_j \{\delta(N, M, j) a_{ji}\}$, and the probability of the most likely state sequence is simply $\max_i \delta(N+1, M+1, i)$, call the maximizing state i^*. The optimal hidden state sequence, given the data, is retrieved in the traceback by starting in i^* and recursively backtracking through $\text{argmax}_i \delta(n-k, m-l, i)$, where $(k, l) \in \{(1, 1), (1, 0), (0, 1)\}$.

Needleman and Wunsch were the first ones to describe an alignment algorithm for two biological sequences using the dynamic programming approach (Needleman and Wunsch, 1970), and although their paper is focused on a very specific problem, it contains the essence of many alignment methods in use today. It is easy to see that by taking logarithms of the parameters we have described, the PHMM Viterbi algorithm becomes a Needleman–Wunsch algorithm with negative scores. If alignments are normalized, some of the scores will be positive (Bucher and Hofmann, 1996). It is also true, that for any set of Needleman and Wunsch scores, a PHMM can be constructed for which the Viterbi algorithm will yield the same alignment as the Needleman–Wunsch algorithm (even for extensions such as affine gap penalties).

There have been countless improvements to the basic algorithm; we point the reader to textbooks such as Durbin *et al*. (1998) and Gusfield (1997) for detailed expositions. One point of note is that there is a linear-space divide and conquer algorithm for pairwise sequence alignment that is crucial for practical applications where memory is a limiting factor in computing large sequence alignments (Hirschberg, 1975).

4.2. Sampling alignments

One of the advantages of using PHMMs for alignment is that operations such as sampling of alignments can be performed in a statistically meaningful way, for example, by sampling from the posterior distribution on the alignments given the observations. This is not only useful for exploring alternatives to the MAP alignment discussed in the previous section but also for utilizing Bayesian methods for parameter estimation. Fortunately, there is an efficient way to sample alignments, which is also memory efficient (Cawley and Pachter, 2003). The algorithm is not well known, and we therefore include it here for completeness.

Consider the alignment of two sequences of lengths N and M, with a simple PHMM that only assigns probabilities for insertions or deletions, which we call w, and has substitution matrices s_{ij} (for observing nucleotides i, j). Let a_{ij} denote the sum of the probabilities of all alignments in which position i in one sequence is

aligned to position j in the other (i.e., the so-called forward variables). Observe that the a_{ij} can be computed using a standard Viterbi-type algorithm with *max* replaced by *sum*. The recursion is

$$a_{ij} = wa_{i-1,j} + wa_{i,j-1} + s_{ij}a_{i-1,j-1} \tag{9}$$

where $i, j \geq 1$ and $a_{0j} = a_{j0} = wj$. Let $v_j = (a_{1j}, a_{2j}, \ldots, a_{Nj})$ be the jth column vector $(0 \leq j \leq M)$. The notation $v_j(i)$ is used to denote a_{ij}. We fix a constant r, and write v_{r+1} in terms of v_r. First, consider the lower-triangular $(N+1) \times (N+1)$ matrix W where the ijth entry of W is $w^{|i-j|+1}$, $i \geq j$ and $w_{ij} = 0$ otherwise. Similarly, let S_r be the $(N+1) \times (N+1)$ matrix with 1 on the diagonal, and $S_r[ij] = s_{jr}$ for $i = j + 1$ and $S_r[ij] = 0$ otherwise. Observe that recursion (1) can be rewritten as

$$v_r = WS_r v_{r-1} \tag{10}$$

In order to sample efficiently, we want to compute v_{r-1} in terms of v_r:

$$v_{r-1} = S_r^{-1}W^{-1}v_r \tag{11}$$

The matrix W is invertible iff $w \neq 0$, which is always the case since $w = e^g$ for some real number g. All the matrices S_r are invertible. Thus, we can solve for v_{r-1} given v_r. Matrix inversion and multiplication are expensive, however, in our case, the equations yield an effective recursive procedure for computing a_{ir} because of the special structure of the matrices. It is easily seen that W^{-1} is a banded matrix with nonzero entries only on the diagonal and off-diagonal, and S_r^{-1} is a lower-triangular matrix. By multiplying them, we obtain the following set of equations for computing v_{r-1} from v_r:

$$\begin{aligned}
v_{r-1}(0) &= \frac{1}{w}v_r(0) \\
v_{r-1}(1) &= \frac{v_r(1)}{w} + v_r(0) - \frac{s_{1r}}{w}v_{r-1}(0) \\
&\vdots \\
v_{r-1}(k) &= \frac{v_r(k)}{w} + v_r(k-1) - \frac{s_{kr}}{w}v_{r-1}(k-1) \\
&\vdots \\
v_{r-1}(N) &= \frac{v_r(N)}{w} + v_r(N-1) - \frac{s_{Nr}}{w}v_{r-1}(N-1)
\end{aligned} \tag{12}$$

Thus, the vector v_{r-1} can be computed in time $O(N)$ from the vector v_r by computing the $v_{r-1}(k)$ in the order $v_{r-1}(0), v_{r-1}(1), \ldots, v_{r-1}(N)$. Although it is possible to derive the recursions (3)–(8) directly from equation (1), we have included the matrix derivation since it is useful in generalizing the backward computation of forward variables to other problems.

The sampling algorithm for randomly selecting an alignment path according to its weight is therefore to first compute v_M using the forward algorithm variation of the Needleman–Wunsch algorithm (*max* replaced by *sum*). This is done using only $O(N)$ memory by keeping only v_{r-1} in memory for the computation of v_r. The samples can then be computed simultaneously by computing $v_{M-1}, \ldots, v_0$ one column at a time and always discarding columns after they have been used (to keep the computations at $O(N)$ memory). The running time of the algorithm for generating k samples is therefore $O(NM + k(N + M))$. The memory requirement, like the Hirschberg algorithm (Hirschberg, 1975), is only $O(N + M)$.

Although we have presented the algorithm for a simple PHMMs, the same method with minor modifications works for more general models.

5. Extensions

5.1. Generalized pair hidden Markov models and alignment

Traditionally, the problems of gene finding and alignment have been treated separately. However, genes and other functional elements in the genome tend to be conserved between related organisms to a higher extent than nonfunctional regions and so strong alignments are an indicator of possible function for the sequences in the aligned regions. Conversely, inferences about sequence function help construct biologically meaningful alignments. Thus, combining the two holds promise to improve both. At a theoretical level, combining gene prediction with alignment is quite simple: the hidden states of the pair HMM are modified to reflect not only the evolutionary history but also the functionality of the bases, and the output states are modified depending on the functional type as well. So, for example, a hidden state might correspond to matching two codons or an output state could correspond to the specific patterns found in splice sites. However, there are serious practical difficulties with this approach. In a PHMM, the number of steps spent in any given hidden state will be geometrically distributed and so, in the case of gene finding, one would expect the lengths of the predicted exons, unlike the lengths of real exons, to have a geometric distribution. This requires using what is referred to as a generalized PHMM. The development of generalized PHMMs was undertaken in Pachter *et al*. (2002). The theory was implemented in a software called SLAM (Alexandersson *et al*., 2003), which aligns and identifies complete exon/intron structures in two related DNA sequences.

5.2. PhyloHMMs and multiple sequence alignment

The hidden Markov model described in Section 3.2. for sequence evolution without gaps can be generalized to multiple sequences related via a phylogeny (McAuliffe, 2004; Siepel and Haussler, 2003). These *phyloHMMs* can also include generalized states, although this introduces complexities when one allows dependencies between neighboring nucleotides in ancestral sequences. In particular, it may no longer be possible to perform efficient MAP inference. In a different direction, multiple sequence alignment by allowing insertions and deletions in ancestral sequences

(without generalized states) leads to interesting models studied by Mitchison (1999), Bruno and Holmes (2001), and others. An interesting future direction for research is the combination of generalized ancestral states with models allowing for insertion and deletion. In other words, it should be interesting to explore generalized phylogenetic Markov Bayesian multinets.

Specialist Review

Information theory as a model of genomic sequences

Chengpeng Bi and Peter K. Rogan
University of Missouri, Kansas City, MO, USA

1. Theory

Shannon and Weaver (1949) developed their theory of information in order to understand the transmission of electronic signals and model the communication system. Gatlin (1972) first described its extension to biology. Information theory is an obvious tool to use in looking for patterns in DNA and protein sequences (Schneider, 1995). Information theory has been applied to the analysis of DNA and protein sequences in several ways: (1) by analyzing sequence complexity from the Shannon–Weaver indices of smaller DNA windows contained in a long sequence; (2) by comparing homologous sites in a set of aligned sequences by means of their information content; and (3) by examining the pattern of information content of a sequence divided into successively longer words (symbols) consisting of a single base, base pairs, base triplets, and so forth.

Some of the most useful applications of molecular information theory have come from studies of binding sites (typically protein-recognition sites) in DNA or RNA recognized by the same macromolecule, which typically contain similar but nonidentical sequences. Because average information measures the choices made by the system, the theory can comprehensively model the range of sequence variation present in nucleic sequences that are recognized by individual proteins or multisubunit complexes.

Treating a discrete information source (i.e., telegraphy or DNA sequences) as a Markov process, Shannon defined entropy (H) to measure how much information is generated by such a process. The information source generates a series of symbols belonging to an alphabet with size J (e.g., 26 English letters or 4 nucleotides). If symbols are generated according to a known probability distribution p, the entropy function $H(p_1, p_2, \ldots, p_J)$ can be evaluated. The units of H are in bits, where one bit is the amount of information necessary to select one of two possible states or choices. In this section, we describe several important concepts regarding the use of entropy in genomic sequence analysis.

1.1. Entropy

Entropy is a measure of the average uncertainty of symbols or outcomes. Given a random variable X with a set of possible symbols or outcomes $A_X =$

$\{a_1, a_2, \ldots, a_J\}$, having probabilities $\{p_1, p_2, \ldots, p_J\}$, with $P(x = a_i) = p_i$, $p_i \geq 0$ and $\sum_{x \in A_X} P(x) = 1$, the Shannon *entropy* of X is defined by

$$H(X) = \sum_{x \in A_X} P(x) \log_2 \frac{1}{P(x)} \tag{1}$$

Two important properties of the entropy function are: (1) $H(X) \geq 0$ with equality for one x, $P(x) = 1$ and (2) Entropy is maximized if $P(x)$ follows the uniform distribution. Here the *uncertainty* or *surprisal*, $h(x)$, of an outcome (x) is defined by

$$h(x) = \log_2 \frac{1}{P(x)} \text{ (bits)} \tag{2}$$

For example, given a DNA sequence, we say each position corresponds to a random variable X with values $A_X = \{\text{A, C, G, T}\}$, having probabilities $\{p_a, p_c, p_g, p_t\}$, with $P(x = \text{A}) = p_a$, $P(x = \text{C}) = p_c$, and so forth. Suppose the probability distribution $P(x)$ at a position of DNA sequence is $P(x = \text{A}) = 1/2$; $P(x = \text{C}) = 1/4$; $P(x = \text{G}) = 1/8$; $P(x = \text{T}) = 1/8$.

The uncertainties (surprisals) in this case are $h(\text{A}) = 1, h(\text{C}) = 2, h(\text{G}) = h(\text{T}) = 3$ (bits). The entropy is the average of the uncertainties $H(X) = \text{E}[h(x)] = 1/2(1) + 1/4(2) + 1/8(3) + 1/8(3) = 1.75$ bits. In a study of genomic DNA sequences, Schmitt and Herzel (1997) found that genomic DNA sequences are closer to completely random sequences than to written text, suggesting that higher-order interdependencies between neighboring or adjacent sequence positions make little contributions to the block entropy.

The entropy (average uncertainty), H, is 2 bits if each of the four bases is equally probable (uniform distribution) before the site is decoded. The information content (IC) is a measure of a reduction in average uncertainty after the binding site is decoded. $IC(X) = H_{\text{before}} - H_{\text{after}} = \log_2|A_x| - H(X)$, provided the background probability distribution $P(\text{before})$ is uniform (Schneider, 1997a). If the background distribution is not uniform, the Kullback–Leibler distance (relative entropy) can be used (Stormo, 2000). The information content calculation needs to be corrected for the fact that a finite number of sequences were used to estimate the information content of the ideal binding site, resulting in the corrected IC, R_{sequence} (Schneider *et al*., 1986). This measures the decrease in uncertainty before versus after the macromolecule is bound to a set of target sequences. Positions within a binding site with high information are conserved between binding sites, whereas low-information content positions exhibit greater variability. The R_{sequence} values obtained precisely describe how different the sequences are from all possible sequences in the genome of the organism, in a manner that clearly delineates the conserved features of the site.

1.2. *Relative entropy*

For two probability distributions $P(x)$ and $Q(x)$ that are defined over the same alphabet, the *relative entropy* (also known as the Kullback–Leibler divergence or

KL-distance) is defined by

$$D_{KL}(P||Q) = \sum_{x \in A_X} P(x) \log \frac{P(x)}{Q(x)} \quad (3)$$

Note that the relative entropy is not symmetric: $D_{KL}(P||Q) \neq D_{KL}(Q||P)$; and although it is sometimes called the KL-distance, it is not strictly a distance (Koski, 2001; Lin, 1991). Relative entropy is an important statistic for finding unusual motifs/patterns in genomic sequences (Durbin *et al*., 1998; Lawrence *et al*., 1993; Bailey and Elkan, 1994; Hertz and Stormo, 1999; Liu *et al*., 2002).

1.3. R_{sequence} versus $R_{\text{frequency}}$

The fact that proteins can find their required binding sites among a huge excess of nonsites (Lin and Riggs, 1975; von Hippel, 1979) indicates that more information is required to identify an infrequent site than a common binding site in the same genome. The amount of information required for these sites to be distinguished from all sites in the genome, $R_{\text{frequency}}$, is derived independently from the size and frequency of sites in the genome. $R_{\text{frequency}}$, like R_{sequence}, is expressed in bits per site. R_{sequence} cannot be less than the information needed to find sites in the genome. With few exceptions, it has been found that R_{sequence} and $R_{\text{frequency}}$ are similar (Schneider *et al*., 1986). This empirical relationship is strongly constrained by the fact that all DNA-binding proteins operating on the genome are encoded in the genome itself (Kim *et al*., 2003).

1.4. Molecular machines

Molecular machines are characterized by stable interactions between distinct components, for example, the binding of a recognizer protein to a specific genomic sequence. The behavior of a molecular machine can be described with information theory. The properties of molecular machine theory may be depicted on multiple levels: on one level, sequence logos, which describe interactions between the molecules (see Figure 1), are equivalent to transmission of information by the recognizer as a set of binary decisions; on another level, the information capacity of the machine, which represents the maximum number of binary decisions (or bits) that can be made for the amount of energy dissipated by the binding event; and finally, the relationship between information content and the energy cost of performing molecular operations (Schneider, 1991; Schneider, 1994). The molecular machine capacity is derived from Shannon's channel capacity (Shannon, 1949). The error rate of the machine can be specified to be as low as necessary to ensure the survival of the organism, so long as the molecular machine capacity is not exceeded. Entropy decreases as the machine makes choices, which corresponds to an increase in information.

The second law of thermodynamics can be expressed by the equation $\mathrm{d}S \geq \mathrm{d}Q/T$. The equation states that for a given increment of heat $\mathrm{d}Q$ entering a volume at some

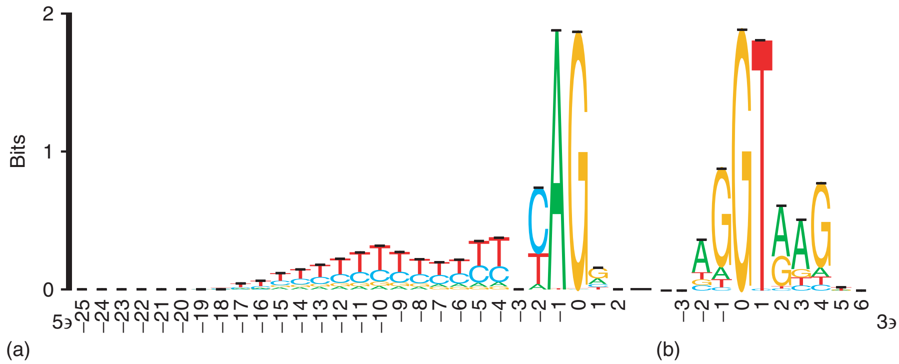

Figure 1 Examples of sequence logos. Models of human (a) 108 079 acceptor and (b) 111 772 donor splice sites derived from both strands of the human genome reference sequence (April, 2003) are shown. A sequence logo visually represents the sequence conservation among a common set of recognition sites, with the height of each nucleotide stack corresponding to the average information content at that position. The height of each nucleotide is proportional to its frequency. Sampling error is indicated by error bar at the top of each stack. The zero coordinate represents the intronic position immediately adjacent to the splice junction. The average information contents (R_{sequence}) of the acceptor and donor sites are respectively, 9.8118 ± 0.0001 bits/site and 8.12140 ± 0.00009 bits/site

temperature T, the entropy will increase dS at least by dQ/T. If we relate entropy to Shannon's uncertainty, we can rewrite the second law in the following form:

$$\varepsilon_{\min} = \kappa_{\text{B}} T \ln(2) \leq \frac{-q}{IC} \text{ (joules per bit)} \tag{4}$$

where κ_{B} is Boltzman constant and q is the heat. This equation states that there is a minimum amount of heat energy that must be dissipated (negative q) by a molecular machine in order for it to gain $IC = 1$ bit of information.

1.5. *Individual information*

The information contained in a set of binding sites is an average of the individual contributions of each of the sites (Shannon, 1948; Pierce, 1980; Sloane and Wyner, 1993; Schneider, 1995). The information content to each individual binding-site sequence can be determined by a weight matrix so that the average of these values over the entire set of sites is the average information content (Schneider, 1997a).

The individual information weight matrix is

$$R_{iw}(b, l) = 2.0 - (-\log_2(f(b, l) + e(n(l)))) \text{ (bits per base)} \tag{5}$$

in which $f(b,l)$ is the frequency of each base b at position l in the binding-site sequences; $e(n(l))$ is a correction of $f(b,l)$ for the finite sample size (n sequences at position l) (Schneider *et al*., 1986). The jth sequence of a set of binding sites is represented by a matrix $s(b,l,j)$, which contains 1's in cells from base b at position l of a binding site and zeros at all other matrix locations. The individual

information of a binding site sequence is the dot product between the sequence and the weight matrix:

$$R_i(j) = \sum_{l} \sum_{b=a}^{t} s(b, j, j) R_{iw}(b, l) \text{ (bits per site)} \tag{6}$$

2. Applications

2.1. *Displaying sequence conservation*

Sequence logos, which display information about both consensus and nonconsensus nucleotides, are visual representations of the information found in a binding site (an example is shown in Figure 1). This is the information that the decoder (i.e., a binding protein) uses to evaluate potential sites in order to recognize actual sites. The calculation of sequence logos uses the assumption that each site is evaluated independently, that is, that there is no correlation between a change in nucleotide at one position with another position, which is reasonable for most genomic sequences (Schmitt and Herzel, 1997). An advantage of the information approach is that the sequence conservation can be interpreted quantitatively. R_{sequence}, which is the total area under the sequence logo and measures the average information in a set of binding site sequences, is related to the specific binding interaction between the recognizer and the site. R_{sequence} is an additive measure of sequence conservation; thus, it is feasible to quantitatively compare the relative contributions of different portions within the same binding site.

Structural features of the protein–DNA complex can be inferred from sequence logos. When positions with high information content are separated by a single helical turn (10.4 bp), this suggests that the protein makes contacts across the same face of the double helix. Sequence conservation in the major groove can range anywhere between 0 and 2 bits depending on the strength of contacts involved, and usually correlates with the highest information content positions (Papp *et al*., 1993). Minor groove contacts of B-form DNA allow both orientations of each kind of base pair so that rotations about the dyad axis cannot easily be distinguished; hence, a single bit is the information content in native B-form DNA (Schneider, 1996). Higher levels of conservation for bases within the minor groove indicate that these positions are accessed protein distortion of the helix, that is, bending accompanied by base-pair opening and flipping (Schneider, 2001).

2.2. *Visualizing individual binding-site information*

Because sequence logos display the average information content in a set of binding sites, they may not accurately convey protein–DNA interactions with individual DNA sequences, especially at highly variable positions within a binding site. The walker method (Schneider, 1997b) graphically depicts the nucleotide conservation of a known or suspected site compared to other valid binding sites defined by the individual information weight matrix (Schneider, 1997a). Walkers apply to a

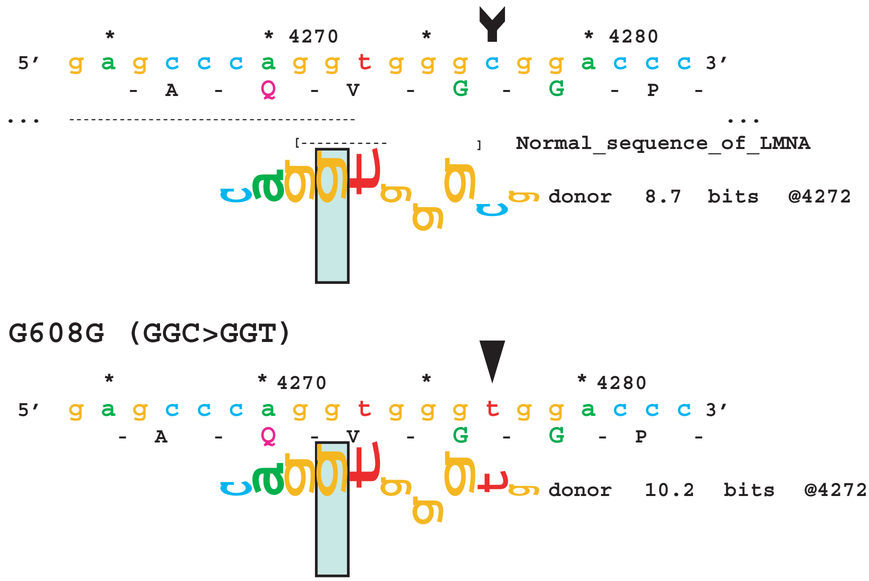

Figure 2 Examples of sequence walkers. A synonymous C > T substitution at codon 608 activates a cryptic donor splice site in exon 11, the *LMNA* gene in patients with Hutchinson–Gifford progeria (Eriksson *et al*., 2003). The walker, shown below the sequence, indicates a preexisting 8.7-bit cryptic site that is strengthened by the mutation to 10.2 bits (≥ 2.8-fold). The height and orientation of each nucleotide correspond to contribution that nucleotide makes to the overall information content in the binding site. The green rectangle indicates the location of valid splice site ($R_i > 0$) and delineates the scale displayed; the lower and upper limits shown are, respectively, −4 bits and +2 bits. Sequence coordinates are from GenBank accession L12401 (4277 C > T)

single sequence (rather than a set of binding sites); only a single letter is visualized at each position of the binding site (Figure 2). The height of the letter, which is in units of bits, represents the contribution of that nucleotide at each position in the binding site by the information weight matrix, $R_{iw}(b,l)$. Evaluation of the R_i value at each position in a genomic DNA sequence is equivalent to moving the walker along that sequence. Walkers are displayed for sequences with positive R_i values, since these are more likely to be valid binding sites (see equation 4 and discussion below). Sequence walkers facilitate visualization and interpretation of the structures and strengths of binding sites in complex genetic intervals and can be used to understand the effects of sequence changes (see below), and engineer overlapping or novel binding sites.

2.3. *Mutation and polymorphism analysis*

Because the relationship between information and energy can be used to predict the effects of natural sequence variation at these sites, phenotypes can be predicted from corresponding changes in the individual information contents (R_i, in bits) of the natural and variant DNA binding sites (Rogan *et al*., 1998; *see also* Article 68, **Normal DNA sequence variations in humans**, Volume 4). For

splice site variants, mutations have lower R_i values than the corresponding natural sites, with null alleles having values at or below zero bits (equation 4; Kodolitsch *et al*., 1999). The decreased R_i values of mutated splice sites indicate that such sites are either not recognized or are bound with lower affinity, usually resulting in an untranslatable mRNA. Decreases in R_i are more moderate for partially functional (or leaky) mutations that reduce but do not abolish splice site recognition and have been associated with milder phenotypes (Rogan *et al*., 1998). The minimum change in binding affinity for leaky mutations is $\geq 2^{\Delta Ri}$ lower fold than cognate wild-type sites. Mutations that activate cryptic splicing may decrease the R_i value of the natural site, increase the strength of the cryptic site, or concomitantly affect the strengths of both types of sites (see Figure 2). Nondeleterious changes do not alter the R_i value of splice sites significantly (Rogan and Schneider, 1995). Increases in R_i indicate stronger interactions between protein and cognate binding sites.

2.4. *Information evolution*

How do genetic systems gain information in a binding site of genomic DNA sequence by evolutionary processes? Schneider (2000) proposed an answer to this question. Given a binding site for an artificial protein, his simulation begins with zero information and, as in naturally occurring genetic systems, the information measured in the fully evolved binding sites (R_{sequence}) is close to that needed to locate the sites in the genome ($R_{\text{frequency}}$).

2.5. *Model refinement*

Information models based on small numbers of proven binding sites may fail to detect valid binding sites and tend to predict R_i inaccurately. Iterative selection of functional binding sites has been used to optimize (Lund *et al*., 2000) and to introduce bias (Shultzaberger and Schneider, 1999) into the frequencies of each nucleotide in computing the information theory–based weight matrices of binding sites. Significant differences between information weight matrices have been determined from their respective evolutionary distance metrics (e.g., see Shultzaberger *et al*., 2001). The effects of model refinements can be monitored by comparing the genome scan results for pairs of successive information weight matrices based on additional binding sites (Gadiraju *et al*., 2003). Other potential applications include the determination of the locations of overlapping binding sites recognized by different proteins and comparisons of binding sites detected with information models of orthologous proteins from different species.

2.6. *Regulatory binding sites*

Information theory–based models have been used in searching for regulatory sites in genomic DNA or RNA sequences of prokaryotes (Hengen *et al*., 1997) and eukaryotes (*see* Article 22, **Eukaryotic regulatory sequences**, Volume 7). The binding sites in prokaryotes include the ribosome binding sites (Shultzaberger *et al*.,

2001), T7 promoters, plasmid replication initiator protein-binding sites (Papp *et al*., 1993) and binding sites for repressors and polymerases (Schneider *et al*., 1986), and cyclic AMP receptor protein (Stormo and Fields, 1989) in *Escherichia coli*.

A bipartite pattern is an independent functional unit on the upstream or downstream side of a regulated gene that is recognized by a protein-binding complex such as a heterodimer. A model built to simulate a bipartite pattern in genomic sequences has left and right motif submodels, plus an associated gap penalty function, $g(d)$ defined as $-\log(n(d)/n)$, where $n(d)$ is the number of sites with gap size d. Shannon's entropy can be used to evaluate such sites by calculating the total information content, IC, given as

$$IC = IC(left|d) + IC(right|d) - g(d) \tag{7}$$

$$IC(m|d) = \sum_{l=1}^{J_m} \left(\log_2 |A_X| - H_{ml}(X)\right), \quad m \in \{left, \quad right\} \tag{8}$$

$$H_{ml}(X) = \sum_{x \in A_X} P_{ml}(x) \log_2 \frac{1}{P_{ml}(x)}, \quad A_X = \{A, C, G, T\} \tag{9}$$

Here J_{m} is the width of motif m and $P_{ml}(x)$ is the probability of x at position l given motif m. The left and right motifs are not allowed to overlap and the gap size (d) is set to a limited range $[d_{\min}, d_{\max}]$ on the basis of empirical observations. The goal is to maximize the total information content that can be reduced to minimize the total Shannon's entropy. We used a Monte Carlo strategy to greedily search the multiple alignment space and find an optimal solution to the bipartite pattern search problem (Bi *et al*., 2004).

We developed a new method for the bipartite cis-regulatory pattern discovery based on minimizing entropy, and applied the method to a set of known PXR/RXRα binding sites in the human genome. The PXR/RXRα heterodimer binding controls the expression of coregulated genes such as *CYP3A4*, which is involved in detoxification of drugs and xenobiotics (*see* Article 70, **Pharmacogenetics and the future of medicine**, Volume 4). This work is an extension of Shultzaberger *et al*. (2001). Using the assumption that two proteins (i.e., PXR and RXRα) cooperatively bind to the bipartite site with constrained spacers, we built models for different motif widths and validated them on the basis of the relative binding strength of a series of test sequences. The results supported our hypothesis that PXR and RXRα transcription factors cooperatively bind to two adjacent motifs with variable spacing (Bi *et al*., 2004).

2.7. Genome-wide analyses

Information weight matrices of binding sites can be developed directly from validated sets of binding sites extracted from genome sequences provided that

the locations of sequence features are accurately annotated. As this is not always the case, we built a genome-wide human splice junction database by initially extracting the coordinates and sequences of donor and acceptor splice regions from both strands of the human genome reference sequence (Rogan *et al*., 2003). After redundant sites were eliminated, the splice site database consisted of 170 144 acceptor and 170 450 donor sites. The information weight matrix was recomputed after each of iteration and scanning of the resultant set of sites. Successive models iteratively utilized the modified matrix by excluding sites with negative R_i values. After eight cycles of refinement, the final models were then defined by 108 079 unique acceptor sites and 111 772 donor sites (sequence logos of model sites are shown in Figure 1).

The average information contents of the acceptor and donor sites are respectively, 9.8 bits/site and 8.1 bits/site. These values are similar to those previously reported by Schneider and Stephens (1990), that is, 9.35 bits for acceptors and 7.92 bits for donors, which were based on about 65-fold fewer splice sites. Individual splice site strengths in the genome have an approximately Gaussian distribution.

3. Prospects for information theory–based analyses of genomic sequences

As the functions for regulatory and expressed nucleic acid sequences are elucidated, it is becoming evident that multiple protein components catalyze these processes. Modeling such molecular machines by information theory will require the development of procedures that account for cooperative and interdependent binding events between two or more recognizers. Frameworks for building multipartite information models will therefore have to incorporate corrections for overlapping sites and mutual information.

There are opportunities to enhance currently available genomic applications by scaling currently available software for information theory analyses (Gadiraju *et al*., 2003) to investigate genome annotation. For example, changes in IC contents due to mutation may be of assistance in prioritizing single nucleotide polymorphisms for functional analyses. It is also possible that comparative genomic analyses of binding sites with orthologous DNA recognition domains from multiple species may reveal possible identities of functionally analogous regulatory sequences in these systems.

Medical genetic applications of information theory–based binding-site models are a promising avenue to improve diagnosis and prognosis of disease-causing mutations (*see* Article 80, **Genetic testing and genotype–phenotype correlations**, Volume 2). Accurate models will be required for use of information theory in a clinical setting. To calibrate individual information measures of protein-nucleic acid binding with the thermodynamic properties of these complexes will require more comprehensive models, that is, based on larger numbers of binding sites spanning a wide range of binding affinities.

Short Specialist Review

Promoter prediction

Vladimir B. Bajic
Institute for Infocomm Research, Singapore

Thomas Werner
Genomatix, Munich, Germany

1. Biological problem and importance for practice and science

Complex processes in cells of living organisms depend on synchronous actions of different groups of genes. Coordination of gene expression is achieved to a large extent by different transcriptional control mechanisms characteristic for each gene and controlling timing, rate, and level of its transcription. Promoters represent genomic regions containing many such regulatory signals. Polymerase II promoters are located at the beginning of the genomic region whose transcription they control. The boundaries of promoters are not very clear, but most important transcriptional signals known today are generally located within the segment of [−2000, +500] relative to the transcription start site (TSS), which often already includes proximal enhancers. The +1 position corresponds to the position of the first transcribed nucleotide.

Accurate promoter determination can help to (1) identify new genes; (2) complement annotation of known genes and identify their 5′ boundary; (3) predict alternative transcripts initiating from additional promoters; (4) localize the most important control region for gene activation; (5) annotate transcriptional regulatory patterns; and (6) determine organizational promoter models of different gene groups, which ultimately can be used to determine the cause–consequence relationships characteristic of different gene activation pathways and gene regulatory networks. The bottom line is that determining the location of promoters can ultimately contribute toward the understanding of the molecular control of activity of the respective genes.

2. Current possibilities for locating promoters

There are two basic categories of techniques allowing for large-scale identification of promoters: experimental and computational methods. The most promising experimental techniques are based on oligo-capping (Maruyama and Sugano, 1994), where the cap structure of mRNAs is selectively replaced by an oligonucleotide,

which subsequently serves as sequencing primer to determine the 5′ sequence of the transcript. More than 83 000 human and murine transcripts have been characterized that way to date. Other experimental techniques include generation of EST sequences and mRNA fragments, and require back-mapping to original DNA genomic sequences. Unfortunately, none of these methods is perfect and even the best (oligo-capping) produces about 20 to 30% false TSS data.

Computational detection of promoters has also advanced considerably recently and is reaching the level where the amount of correct promoter prediction is severalfold or higher than the amount of false-positive promoter prediction in large-scale genomic searches (Scherf *et al*., 2000; Bajic and Seah, 2003).

3. Current computational solutions

We will make comments about promoter prediction programs (PPPs) for eukaryotic promoters developed or significantly modified in 1999 and after. Two reviews (Fickett and Hatzigeorgiou, 1997; Prestridge, 2000) discussed earlier PPP solutions. We will comment on CONPRO (Liu and States, 2002), CpGProD (Ponger and Mouchiroud, 2002), CpG-Promoter (Ioshikhes and Zhang, 2000), Dragon Promoter Finder (DPF) (Bajic *et al*., 2003), Dragon Gene Start Finder (DGSF) (Bajic and Seah, 2003), Eponine (Down and Hubbard, 2002), First Exon Finder (FirstEF) (Davuluri *et al*., 2001), McPromoter (Ohler *et al*., 2001), NNPP2.1 (Reese, 2001), Promoter2.0 (Knudsen, 1999), PromoterInspector (Scherf *et al*., 2000), PromH (Solovyev and Shahmuradov, 2003), and the system of Hannenhalli and Levy (SHL) (Hannenhalli and Levy, 2001).

4. Biological signals

There are several types of biological signals utilized to enhance computational promoter predictions.

The most significant are CpG-islands (Bird *et al*., 1986), relatively short stretches of DNA characterized by high amount of CpG dinucleotides containing high amounts of unmethylated C nucleotides. Unmethylated C nucleotides facilitate factor binding to genomic DNA during transcriptional activation and initiation. CpG-islands are frequently found close to the gene starts and thus close to promoters. CpG-islands are characteristic for a large proportion of vertebrate genomes (Cross and Bird, 1995). PPPs that use the concept of CpG-island are CpGProD, CpG-Promoter, DGSF, FirstEF, and SHL.

Another significant characteristic, at least of the human genome, is an elevated GC content around the TSS, across the first exon, and around the first splice donor site as opposed to other parts of the genome (Louie *et al*., 2003). These properties are only partially related to CpG-islands. Moreover, there is a strong bias in the nucleotide content in 5′ region of genes (Louie *et al*., 2003; Majewski and Ott, 2002), including CpG dinucleotide and GGG trinucleotide. PPPs that utilize different GC content of promoters are DPF, DGSF, Eponine, FirstEF, and together with other features also PromoterInspector.

The third characteristic of promoters that is more universal across different taxa are sets of specific combinations of promoter elements (PEs) (transcription factor binding sites and promoter boxes, and their combinatorial and positional distribution patterns) for individual promoters and promoter groups of coregulated genes (e.g., Fessele *et al*., 2002). PPPs that use different combinations of promoter elements are McPromoter, NNPP2.1, and Promoter2.0.

The fourth characteristic of promoter regions versus nonpromoter regions can be found in different densities of potential PEs in these regions. Independent studies of authors suggest a number of overrepresented PE patterns, such as E2F, ETF, Elk-1, and ZF5, in human promoters as opposed to nonpromoters. However, as such overrepresentation is method/data dependent in most cases, this may impact performance of PPPs that utilize this promoter characteristic.

In addition, there are some other physicochemical properties that distinguish promoters from nonpromoters, such as DNA bendability, propeller twist, and so on (Ohler *et al*., 2001). A PPP that uses these properties in combination with other features is McPromoter.

PPPs employ numerous types of biological information, and currently, the most efficient systems utilize some of the key biological characteristics of promoter regions or their combinations.

5. Implemented technology

PPP implementations include position weight matrices and their higher-order derivatives (in DPF, DGSF, FirstEF, Eponine); various artificial intelligence approaches such as artificial neural networks (DPF, DGSF, McPromoter, NNPP2.1, Promoter2.0, PromoterInspector), Interpolated Markov Models (McPromoter), and relevance vector machine (Eponine); some standard statistical techniques such as linear (SHL, PromH), and quadratic discriminant analysis (FirstEF, CpG-Promoter); as well as comparison with orthologous promoter sequences (PromH). Some solutions use combinations of different separate solutions (CONPRO).

6. Information provided to end users

The existing PPPs provide different information to the end user. Prediction of promoters can be strand-specific (DPF, DGSF, Eponine, FirstEF, CONPRO, McPromoter, NNPP2.1, Promoter2.0, PromH) or non-strand-specific (CpG-Promoter, CpGProD, SHL, PromoterInspector). In the first case, the direction of the body of the transcript is predicted, while in the latter case only the genomic locations of its 5′ end is predicted, with no direction for the transcript. Some programs attempt to predict the actual TSS locations (DPF, DGSF, Eponine, FirstEF, CONPRO, McPromoter, NNPP2.1, Promoter2.0, PromH), while others predict a region expected to contain a TSS (CpG-Promoter, CpGProD, DGSF, SHL, PromoterInspector). In addition to these basic data, some PPPs also provide additional information such as potential TSBSs in the region of interest (DPF, DGSF, PromH), information on

other genomic signals, such as first donor (FirstEF), CpG-islands (FirstEF, CpG-ProD, CpG-Promoter), genomic location corresponding to the translation initiation codon (DPF), and so on.

7. Current performance

We tested several PPPs on three whole human chromosomes (4, 21, and 22). Details of the experiment were as presented in Bajic and Seah (2003), with the only difference being that we merged predictions of individual systems if they were no more than 1000 nucleotides apart (except for PromoterInspector). The performances in percentage for PPPs are given in the form (sensitivity, positive predictive value): DPF (for threshold 0.5) (80.70, 22.21), DGSF (65.04, 77.27), Eponine (41.04, 85.20), FirstEF (78.43, 48.08), McPromoter (for threshold −0.005) (55.65, 70.95), NNPP2.1 (for threshold 0.99) (60.52, 7.40), and Promoter2.0 (60.52, 4.61). PromoterInspector achieved (42, 52) and (11, 96) on the complete human and mouse genomes, respectively, measured relative to the known transcripts (not gene numbers) and including a large amount of alternative transcripts usually not considered.

8. Future solutions: the next generation

Since the large-scale localization of TSSs in mammalian genomes has reached maturity and levels of ~80% of correct promoter predictions falling into region [−500, +500] relative to real TSS (Bajic and Seah, 2003), there are two immediate next targets for future developments of promoter prediction. One goal would be the more position-accurate TSS prediction, hopefully in the range of [−20, +20] relative to the real TSSs, and the ability to accurately distinguish alternative TSSs. The second goal, naturally, is to increase the sensitivity of predictions while preserving the specificity reached so far. This will be very important in the light of a huge amount of alternative transcripts representing an important body of biologically relevant information.

Another issue will be the extension of high-accuracy predictors to nonmammalian species, including other vertebrates, invertebrates, and plants. These extensions may not necessarily be simple, as, for example, in *Fugu rubripes* the GC properties of promoters and nonpromoters are very different compared to the human genome. Many of the nonmammalian species do not have high proportion of unmethylated CpG-islands characterizing gene starts, while typical promoter elements such as TATA and CCAAT boxes may appear in completely different proportions than in mammalian genomes. Furthermore, the GC content of different genomes will influence our ability to effectively search for TSSs computationally.

Short Specialist Review

Operon finding in bacteria

Maria D. Ermolaeva
The Institute for Genomic Research, Rockville, MD, USA

Bacterial genes are often organized into multigene transcriptional units (TUs), a series of genes that are transcribed together into one messenger RNA (mRNA) molecule. A TU starts with a promoter, which initiates transcription, and ends with a terminator, which terminates transcription (Figure 1a). The expression of the genes in a TU is controlled by one set of regulatory gene(s), which is often located nearby. The term “operon” was originally defined to include both the TU and the associated regulatory genes; however, today, the term is often used to refer only to a set of cotranscribed genes. This is especially common in computational genomics, where it is often necessary to simplify the model of an operon in order to make computational predictions. Indeed, the model shown in Figure 1(a) is simplified in a number of other aspects, too. Additional promoters and terminators may be located between the cotranscribed genes, and genes may be cotranscribed in some conditions and transcribed separately in other conditions. These details usually cannot be captured by operon-prediction methods and, therefore, they are not discussed here. Genes that are transcribed separately from other genes can be considered as one-gene TUs.

Finding TUs computationally is a difficult task; the predictions are much less accurate than the gene predictions themselves. The apparent solution would be to find the stretches of genes located between a promoter and terminator; however, this requires accurate knowledge of promoters and terminators, which are usually at least as difficult to predict as operons. The only exception here is rho-independent terminators, which have a distinctive structure and can, for some species of bacteria, be predicted accurately.

While it is difficult to predict TUs’ boundaries, it is possible to make a rough estimate of their number in a genome. This estimate can be done using only gene predictions, which are usually more than 95% accurate in bacteria. Here, we have to introduce an additional term, “directon” (Salgado *et al*., 2000), which is a set of genes located consecutively, one after another, on the same DNA strand. All genes of a TU always belong to the same directon because genes must be on the same strand in order to be transcribed together. A directon may include one or more TUs and single genes (one-gene TUs). Figure 1(a) shows a directon that consists of one TU – the flanking TUs have the opposite orientation; that is, they are located on the opposite DNA strand. Figure 1(b) shows another possible situation, where the two neighboring TUs have the same orientation and belong to the same operon. If the orientation of all TUs were completely independent of their flanking TUs,

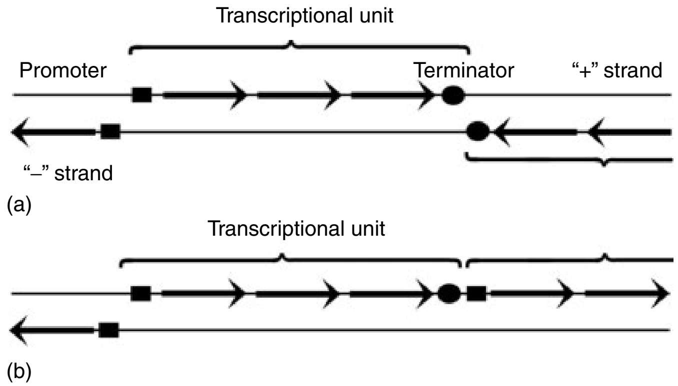

Figure 1 A scheme of a transcription unit. (a) The neighboring transcription units are located on the opposite DNA strand. (b) At least two consecutive transcription units are located on the same DNA strand, making it difficult to locate a boundary between them

then the average directon would have two TUs (Ermolaeva *et al*., 2001). Therefore, the size of an average TU would be half the average directon size, which can be easily calculated from the gene predictions. (Note that single genes are counted as one-gene TUs.) Most bacterial and archaeal genomes have some strand bias, with more genes located on the leading strand of replication than on the lagging strand. In this case, an average TU size t can be calculated as

$$t = \frac{d}{1+b} \tag{1}$$

where d is the average directon size and b is the strand bias, calculated as the number of genes on the leading strand divided by the number of genes on the lagging strand. We prove this as follows. First, the probability that a randomly chosen TU would be located on the leading strand is

$$p = \frac{b}{1+b} \tag{2}$$

The probability that a randomly chosen directon has exactly n TUs is the probability that the first n TUs are located on the leading strand and the next TU is on the lagging strand plus the probability that the first n TUs are located on the lagging strand and the next TU is on the leading strand:

$$P(n) = p^n \cdot (1-p) + (1-p)^n \cdot p \tag{3}$$

The average number of TUs in a directon is the sum of all possible directon sizes multiplied by their corresponding likelihoods:

$$t = \sum_{n=1}^{\infty} P(n) \cdot n \tag{4}$$

Combining equations (2), (3), and (4) and reducing the infinite summation yields equation (1).

The next logical step is to find the TU boundaries, that is, to predict which of the neighboring genes are transcribed together and which pairs of the neighboring genes belong to different TUs. For genes located on opposite DNA strands, the answer is obvious: they belong to the different TUs because they cannot be transcribed together. Consecutive genes that are located on the same DNA strand may belong to the same or different TUs.

TU and operon boundaries can, in some cases, be found using the knowledge of metabolic pathways and gene functions (Zheng *et al*., 2002). Genes that belong to the same metabolic pathway are often regulated together, and are located in the same operon. This method, however, can only be applied to well-studied genes with known metabolic pathways. Another method that relies on experimental data is described in Sabatti *et al*. (2002). Genes within a TU are transcribed together and, therefore, they have similar levels of expression. Microarray experiments allow us to measure the expression of genes in different conditions and to find genes with correlated expression levels. Although correlated expression does not directly imply that genes belong to the same operon, when coupled with those genes' adjacency information on the genome it can provide strong evidential support. The main shortfall of this method is the difficulty, using current technology, of obtaining accurate and reproducible gene expression measurements, which means that a large number of experiments are required to detect the correlation.

The two methods described above require extensive experimental data to support any conclusions about TUs. In addition, there are a few "purely computational" approaches that only rely on the DNA sequence data and gene predictions. Two such methods are described below.

The first method is based on calculating intergenic distances; that is, the distances between neighboring genes (Salgado *et al*., 2000). As illustrated in Figure 1(b), two neighboring genes must be separated by a terminator and a promoter, if they belong to different TUs. Thus, the distance between such genes is usually longer than the intergenic distances within TUs. Thus, genes that are located close to each other are likely to belong to the same TU, while genes that are separated by hundreds of nucleotides are (in prokaryotes) likely to have a TU boundary between them. This amazingly simple method has an impressively high (compared with the other methods) accuracy of 82% for the *Escherichia coli* genome. This method can be also used for other bacterial and archaeal genomes (Moreno-Hagelsieb and Collado-Vides, 2002), but its accuracy is not always clear. Different genomes have different distributions of intergenic lengths, either due to fundamental differences in their biology or, possibly, to differences in methods of computational gene prediction. Figure 2 shows such distributions for three bacterial genomes: *E. coli*, *Thermotoga maritima*, and *Synechocystis*. In the figure, *E. coli* has a distinctive maximum for short intergenic distances, most of which are located within TUs. Similarly, *T. maritima* has an even higher percentage of short distances, but *Synechocystis* appears to have few short intergenic distances.

It is not clear whether the genomes with longer average intergenic distances have fewer operons or whether the distances between genes within operons are longer. Figure 3 shows that there is a weak correlation (Pearson correlation coefficient 0.26)

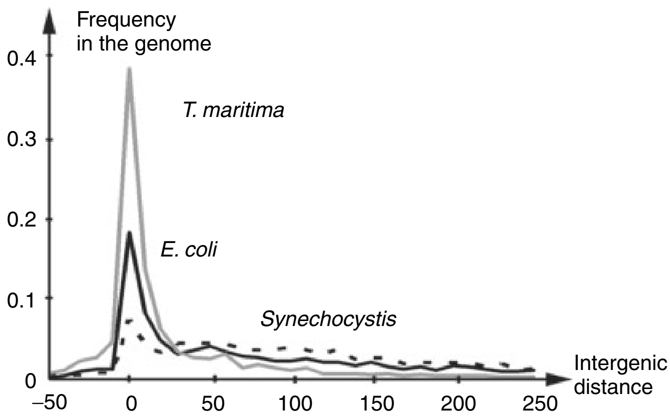

Figure 2 Frequency of intergenic distances (in 10 bp bins) in three bacterial genomes. Only distances between genes located on the same DNA strand were considered

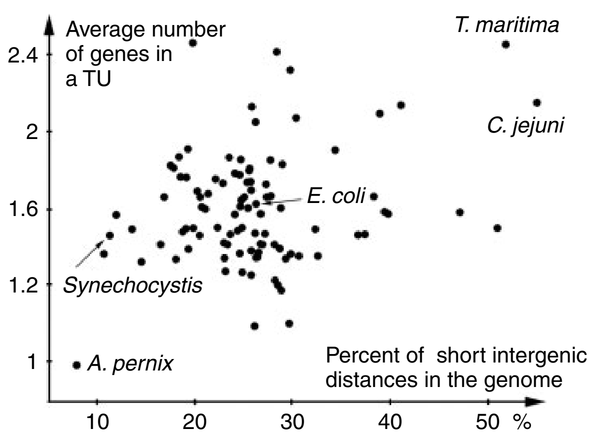

Figure 3 Each dot represents one sequenced bacterial or archaeal genome. Axis x shows percent of short intergenic distances (from −5 to 15 bp) in the genome (only distances between genes located on the same DNA strand were considered) and axis y shows the average number of genes in a transcriptional unit, calculated using equation (1)

between the percent of short distances in a genome and the average number of genes in a TU (calculated using equation (1)). We should mention here that intergenic distances may vary significantly due to the accuracy of placement of gene start sites (i.e., the initial ATG start codon), whose prediction varies dramatically depending on the gene prediction method used. This bias, however, does not appear to be the sole reason for the weak correlation: using subsets of genes whose start sites have greater accuracy (known from sequence homology with genes in other species and ribosome binding sites predictions) has only a small effect on the overall picture.

The second, more computationally sophisticated operon-finding technique is based on finding conserved gene clusters (Bansal, 1999; Overbeek *et al*., 1999; Huynen *et al*., 2000; Snel *et al*., 2000; Ermolaeva *et al*., 2001; Mering *et al*.,

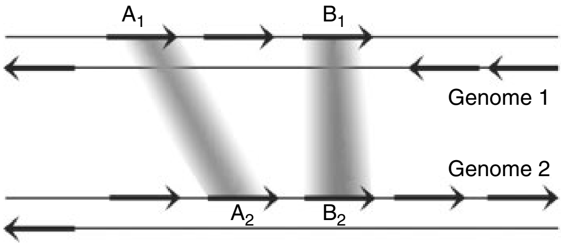

Figure 4 Genes A and B are located nearby, within one directon in both genomes, forming a conserved gene cluster. A_1 is ortholog of A_2, and B_1 and B_2 are also orthologs

2003). Bacterial genomes often reshuffle their genes, changing gene order and orientation. Even such evolutionary related genomes as *E. coli*, *Haemophilus influenzae*, and *Vibrio cholerae* have completely different gene orders when viewed at a genome scale. Genes that belong to the same operon – and that are regulated by the same mechanisms – are under greater selective pressure to remain together, even as other genes are shuffled. Therefore, when conserved gene clusters are observed in evolutionarily distant genomes, one can make the inference that these clusters are likely to represent TUs. Figure 4 shows a scheme of a conserved gene cluster that consists of two genes.

The specificity of these methods depends on the extent of gene cluster conservation, and may be as high as 98% or higher (Ermolaeva *et al*., 2001) if the gene cluster is shared by at least a few evolutionary distant genomes. Such methods, however, can locate only a portion of all operons, because many operons are present in only one or two currently sequenced genomes. Fortunately, the predictive power of this comparative genomics strategy will improve steadily over time, as the sequences of more bacterial and archaeal genomes become available.

Short Specialist Review

Gene structure prediction in plant genomes

Volker Brendel
Iowa State University, Ames, IA, USA

1. Introduction

In eukaryotes, the presence of intervening sequences (introns) within most genes makes the problem of computational gene structure prediction distinct from (and harder than) the same problem in prokaryotes. However, even among eukaryotes, the problem is varied beyond the basic need for species-specific training of algorithm parameters. For example, introns are rare in yeast genes, and, where found, they typically bear highly conserved signature patterns for splicing signals that make identification easy. The purpose of this short review is to discuss approaches to gene identification in plants. There are two reasons why this task is somewhat different from the same task in animals. The first reason is biological. Introns in plant genes have a similar length distribution as exons (Brendel *et al*., 1998). In particular, there appear to be none of the very long introns that confound gene prediction in vertebrates. The second reason is pragmatic. Expressed Sequence Tag (EST) sequencing and whole-genome as well as genome-survey sequencing is in progress for dozens of plant species, all of which appear closely enough related that gene identification in any given species can very efficiently leverage annotation and sequence information from all the other species. In practice, a combination of ab initio gene prediction, spliced alignment, and expert annotation will, in most cases, produce highly reliable protein-coding gene structures. Identification of noncoding RNA genes such as *snoRNA* and *miRNA* genes might prove a much harder problem (Chen *et al*., 2003; Reinhart *et al*., 2002; Llave *et al*., 2002; Marker *et al*., 2002).

1.1. Ab initio algorithms for plant gene finding

Most of the experience with computational gene structure prediction in plants was derived from annotation and reannotation of the Arabidopsis genome. The initial annotation (Arabidopsis Genome Initiative, 2000) was achieved with specially trained gene-finding programs such as GENSCAN (Burge and Karlin, 1997), GeneMark.hmm (Lukashin and Borodovsky, 1998), and GlimmerA (Salzberg *et al*., 1999). These programs derive their predictions “ab initio”: the input consists only of the genomic DNA to be annotated, and gene structures are derived on the

basis of models for exons, introns, and transcription and splicing signals (reviewed in Mathé *et al*., 2002). The underlying methods, also called "intrinsic methods", are similar between the various programs; however, combinations of the programs have been shown to perform better than any single program (Murakami and Takagi, 1998; Pavy *et al*., 1999). The performance of these methods has been thoroughly tested (Pavy *et al*., 1999). At best, exon level sensitivity and specificity were found around the 80% mark, and fewer than half of the predicted gene structures were completely correct. While unsatisfactory in terms of current understanding of gene structure and transcriptional and posttranscriptional control, in practice, such approximate annotations are highly useful because they immediately provide a glimpse of the gene space. Biologists can often find their genes of interest by a simple BLAST search (Altschul *et al*., 1997) against the annotated genes and then refine the respective gene models by more detailed analysis. On a large scale, reannotation efforts (Wortman *et al*., 2003) rely on approaches discussed in the next two sections.

1.2. Spliced alignment with cDNAs and ESTs

Full-length cDNA sequencing provides the most direct way for gene structure identification, because by definition the cDNA residues derive from exons in the genomic sequence. The problem of threading a cDNA sequence back into its corresponding genomic DNA is known as *spliced alignment*. The alignment task is straightforward in the absence of significant differences between the cDNA and the genomic DNA (some level of mismatch would simply result from sequencing errors or differences between DNA sources). A number of programs are available to this end, including dds/gap2 (Huang *et al*., 1997), sim4 (Florea *et al*., 1998), GeneSeqer (Usuka *et al*., 2000), and BLAT (Kent, 2002). In practice, large-scale EST-sequencing projects often provide the first view of a plant's gene space. If not accompanied by a genome-sequencing project, the ESTs are typically clustered and assembled on the basis of sequence similarity to derive nonredundant sets of putative transcripts ("unigenes"; e.g., Quackenbush *et al*., 2001; Dong *et al*., 2004). Otherwise, inherent problems of EST clustering (limited power to detect overlap and to distinguish duplicated genes, chimeric clones) can be largely eliminated by spliced alignment of ESTs onto the genome and subsequent assembly of these spliced alignments to complete gene structures (Zhu *et al*., 2003; Haas *et al*., 2003). In many cases, incorporation of splice site prediction into the derivation of optimal spliced alignments allows the use of nonnative ESTs for gene structure prediction (Brendel *et al*., 2004). This approach appears very promising, given the large combined EST resources across all plant species.

1.3. Spliced alignment with proteins

Although gene order is not necessarily conserved between even closely related plant species (Tarchini *et al*., 2000; Fu and Dooner, 2002), the proteomes of different plants are estimated to be more than 90% conserved (Bennetzen, 2000).

This suggests a successful complementary strategy to gene identification based on spliced threading of protein sequences into genomic DNA thought to encode a homologous protein. The implicit conservation of the reading frame across predicted coding exons makes the algorithms for such alignment tasks more complex than in the cDNA/EST spliced alignment case. Programs such as AAT (Huang *et al*., 1997) and GeneSeqer (Usuka and Brendel, 2000) can be used, provided close-enough homologs can be identified as probes. In practice, good results can be achieved with a combination of cDNA/EST and protein spliced alignments (Schlueter *et al*., 2003). This derives from the fact that EST coverage is mostly from the 5′- and 3′-ends of a gene, regions that are the most difficult to predict by protein spliced alignment because of natural variation in N- and C-termini of proteins, whereas the EST-sparse internal exons are best predicted with homologous proteins (Usuka and Brendel, 2000). The limitations of this approach are, first, that this method obviously does not apply to genes that are specific to a given species; and, second, that poor choices of the protein probe will lead to unreliable predictions. The latter problem could be exacerbated if the probes themselves are erroneously predicted proteins, thus potentially propagating annotation errors (Gilks *et al*., 2002).

1.4. Combined approaches and user-contributed annotations

The problem of automated computational gene structure prediction remains challenging. In particular, it is difficult to weight different sources of prediction and evidence to derive a consistent prediction. A human expert can often easily enough distinguish solid and plausible evidence from the spurious or mistaken. Examples of this include an unmasked poly-A tail in an EST sequence matched erroneously to an adenine-rich segment of genomic DNA in a spliced alignment, a missed U12-type intron, or a chance alignment of a low-complexity protein region. But large-scale applications of computational gene structure prediction will be hard-pressed to find program parameter settings that work for the special cases. It is to be hoped that wide community participation in expert-based gene structure annotation and editing will result in highly reliable annotations for the fully sequenced plant genomes, providing a foundation for further development of computational approaches (allowing model training on error-free data) and of homology-based annotation of subsequently sequenced genomes.

Eukaryotic regulatory sequences

Mathias Krull
BIOBASE GmbH, Wolfenbüttel, Germany

Edgar Wingender
University of Göttingen, Göttingen, Germany
BIOBASE GmbH, Wolfenbüttel, Germany

1. Introduction

In metazoan organisms, cells have to express specific sets of genes to maintain cellular housekeeping as well as the cell's specific identity and to respond to external stimuli that induce developmental differentiation, growth, and survival. To achieve the regulatory specificity, transcription of eukaryotic genes is controlled by a complex modular machinery of interacting proteins, which is not yet completely understood. The proteins, termed *transcription factors*, mediate their effects by targeting specific sites on the DNA nucleotide sequence, the regulatory sequences. The location and distance to the regulated gene differs with the type of the control element. Elements that constitute the core promoter and bind the RNA polymerase II (Pol II) and the general transcription factors are situated in the close vicinity of the transcription start site (TSS) (Butler and Kadonaga, 2002), whereas enhancers can be as distant as 50 kb up- or downstream from the TSS.

The DNA sites a transcription factor binds to do not have a unique sequence as the sites for most restriction enzymes (Stormo, 2000). The sequence patterns are degenerate so that a factor recognizes a family of sequences with variable affinity. In general, the sequences are short (5–15 bp) and occur frequently in the genome by chance (Bailey and Noble, 2003). This makes any in silico identification of "real" functional sites difficult and implies that additional mechanisms are involved in specific transcriptional regulation. According to the commonly accepted models, these are mainly the combination of sites to cis-element clusters (Frith *et al*., 2001; Bailey and Noble, 2003) and the accessibility of the clusters for transcription factors that is regulated by DNA methylation and chromatin structure (Wagner, 1999).

We give a short overview on the best characterized types of regulatory sequences and modules and on computational methods that have been applied for their genome-wide prediction, a knowledge that would bring enormous benefits for uncovering the network of transcription regulation and identifying gene targets for therapeutic intervention (Frith *et al*., 2001). Currently, prediction of promoters (*see*

Article 19, **Promoter prediction**, Volume 7) is far more successful in comparison with enhancer prediction, which is not yet possible.

2. Regulatory sequences and clusters

The core promoter of a eukaryotic gene is defined as the minimal part of contiguous DNA that is recognized by the preinitiation complex (PIC) and is sufficient for transcription initiation. The PIC consists of Pol II and the general transcription factors TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH (Fickett and Hatzigeorgiou, 1997) that are multisubunit complexes themselves. The most prominent regulatory site is the TATA box that is typically located 25–30 bp upstream of the TSS. It binds TBP (a part of TFIID), but as all other sites it is not universal and is present only in a subset of core promoters (Butler and Kadonaga, 2002). The initiator (Inr) encompasses the TSS and is recognized by several transcription factors. The downstream core promoter element (DPE) is frequent in TATA-less promoters and is located at an invariant distance to the Inr 28–32 bp upstream of the TSS, whereas the TFIIB recognition element (BRE) is present immediately upstream of some TATA boxes (Butler and Kadonaga, 2002). CpG islands are stretches of GC-rich DNA (size of 0.5 to 2 kb) that contain multiple GC-box motifs as target sites of Sp1 and related transcription factors. They can typically be found in TATA and DPE-free core promoters of housekeeping genes and initiate transcription from multiple weak start sites. Thus, core promoters are different combinations of control elements and can as such be recognized by specific enhancers (Butler and Kadonaga, 2002).

The proximal promoter is the region ranging from −250 to +250 bp in relation to the TSS (Butler and Kadonaga, 2002). Together with the core promoter, it constitutes the promoter. It contains multiple binding sites for a subset out of the 2000 transcription factors estimated for humans. Alone, some of the sites are nonfunctional, but rather need the synergistic/antagonistic combination with one or more additional sites and are called *composite elements* (Kel-Margoulis *et al*., 2002). Single sites and composite elements tend to be clustered as higher order cis-regulatory modules, which may be a key for efficient prediction (Bailey and Noble, 2003). This model is supported by the fact that transcription factors often form multimeric functional complexes.

Enhancers are long distance (up to +/− 50 kb) regulatory elements with a length of 50–1500 bp that harbor multiple protein-binding sites targeted by a multiprotein complex, the enhancesome. The enhancesome can augment gene transcription via interaction with the promoter-bound multiprotein complex (Blackwood and Kadonaga, 1998). When the effect is repressive, the enhancer is called a *silencer*.

To prevent that enhancers regulate other unrelated genes, their influence is blocked by special regulatory sequences, termed *insulators*. They also protect a gene against the inactivating impairment by adjacent heterochromatin (Burgess-Beusse *et al*., 2002).

Also acting as boundary elements are the scaffold/matrix-attached regions (S/MARs), which are the anchor points for chromatin loops at scaffold/matrix proteins. Amongst other proteins, they also bind transcription factors and are involved in gene expression regulation (Schübeler *et al*., 1996).

Another distal regulatory sequence is the locus control region (LCR) that has influence on several genes of a locus, for example, the globin locus. For exerting its effects, it recruits a holocomplex out of chromatin-modifying enzymes, coactivators, and transcription factors that can make promoters accessible and competent for subsequent transcriptional activation by other control elements (Levings and Bungert, 2002; Blackwood and Kadonaga, 1998).

3. Prediction

A transcription factor tolerates significant variation in the sequences of its DNA binding sites. Different formats have established that try to reflect this pattern of binding specificity: consensus sequences, positional weight matrices (PWM), and profile hidden Markov models (HMM). A consensus sequence indicates the most preferred base at each position, also including the IUPAC alphabet for ambiguous bases. Its utility for site prediction has limitations due to the ambiguities in the pattern that give rise to a high number of false-positive matches on one side (Stormo, 2000) and to its rigidity causing a high rate of false-negatives on the other (Quandt *et al*., 1995). A PWM assigns a weight to all bases at each position of a site and returns a site score that is the sum of these weights. Ideally, the score gives an estimation of the free energy of the protein–DNA binding (Fickett and Hatzigeorgiou, 1997). A prerequisite, and often a bottleneck, for matrix construction is the availability of an adequate number of experimentally proven binding sites for a particular factor. Collections of known binding sites can be obtained from databases such as TRANSFAC (Matys, 2003).

HMMs are generative models for describing the probability distribution over a family of sequences. They are suited to model substitutions, insertions, and deletions very well, with the limitation that dependencies between particular positions in the sequence cannot be included (Eddy, 1998).

PWMs and profile HMMs can identify in vitro target sequences accurately but cannot predict sites with in vivo function alone. Besides knowledge about chromatin structure and protein–protein interactions, the identification of regulatory clusters and the construction of predictive models can help. Several algorithms for predicting regulatory clusters have been proposed (e.g., Bailey and Noble, 2003; Frith *et al*., 2001; Wagner, 1999). They can be grouped in three classes, two of which are generative in that they rely upon a rule set of a cluster model. They use a sliding window approach and HMMs, respectively. The third approach is discriminative and models the difference between regulatory and nonregulatory sequences (Bailey and Noble, 2003).

Phylogenetic footprinting for the identification of conserved regions in orthologous gene sequences may give supporting evidence for predicted transcription factor binding sites (Lenhard *et al*., 2003). Sets of coregulated genes identified by gene expression arrays are important sources for the systematic analysis of regulatory sequences by pattern matching and approaches as explained above, but also for pattern identification algorithms that may find new regulatory elements (*see* Article 28, **Computational motif discovery**, Volume 7).

Short Specialist Review

Alternative splicing in humans

John G. Conboy and Inna Dubchak
Lawrence Berkeley National Laboratory, Berkeley, CA, USA

1. Introduction

In the human genome, the protein coding sequence of most genes is organized into discrete blocks of sequence, the exons, which are interrupted by noncoding sequences called introns. Exons and introns are transcribed together as long nuclear pre-mRNAs that must be spliced so as to excise the introns and ligate the exons, forming mature mRNAs that are exported to the cytoplasm for translation. For small genes, this process of RNA splicing is often hard-wired so that the same array of exons is always joined to create a single unique mRNA. Many large eukaryotic genes, in contrast, exhibit alternative competing pathways for splicing, generating multiple mRNA isoforms that differ with respect to inclusion or exclusion of selected exons or parts of exons. Moreover, because alternative exons can encode unique peptides or introduce new translation initiation or termination signals, any aspect of protein structure and function may be affected, having important physiological impacts on virtually every major cellular process. In recognition of the critical role of splicing as a key mediator of gene expression, its discovery was celebrated with the 1993 Nobel Prize award in Physiology or Medicine to Richard Roberts and Phillip Sharp.

Others have reviewed the structure and function of the eukaryotic spliceosomal machinery and the biochemical mechanisms involved in catalysis of the splicing reactions (Black, 2003). Here, we will focus briefly on the importance of alternative splicing in the human genome. It is now known that a majority of human genes are alternatively spliced with respect to one or more exons (Modrek and Lee, 2002), and that this phenomenon allows a relatively small genome to encode an enormously complex proteome. A number of efforts are under way to catalog and classify human alternative splicing events on a genome-wide basis, and to compare alternative splicing among genomes of other species (e.g., Lee *et al*., 2003; Nurtdinov *et al*., 2003; Pospisil *et al*., 2004; Thanaraj *et al*., 2004). Some splicing events are poorly conserved phylogenetically and may represent experiments of nature, while others are very highly conserved through evolution and likely regulate important cellular functions. Many conserved splicing events are tightly regulated in cell type– and differentiation stage–specific patterns, so that individual exons or sets of exons can be switched on or off in response to appropriate environmental signals. Moreover, regulation of alternative splicing is functionally coupled to

other RNA processing events including transcription initiation and polyadenylation (Hirose and Manley, 2000; Maniatis and Reed, 2002). A major challenge in the splicing field remains identification and characterization of the regulatory networks that control alternative splicing switches and thereby play important roles in defining the specialized properties of differentiated cells.

2. Cis-acting regulatory sequences in the genome

The decision to activate splicing of an alternative exon requires mechanism(s) for recruiting spliceosomal machinery to the appropriate splice sites, a daunting task given the observed degeneracy of splice site consensus sequences and the abundance of cryptic splice sites in the genome. The cellular splicing machinery meets this challenge by employing not only the splice sites themselves but also accessory regulatory elements in the exon and/or its flanking introns, for the process of "exon definition" (Robberson *et al*., 1990). Analogous to regulatory elements that stimulate or repress transcription, positively acting enhancer elements and negatively acting silencer elements can exert dramatic effects on the control of pre-mRNA splicing by promoting or inhibiting spliceosome recruitment. While exons are generally enriched in enhancers and introns contain abundant silencers (Cartegni *et al*., 2002; Fairbrother and Chasin, 2000; Fairbrother *et al*., 2002), tissue-specific alternative exons often contain both types of elements as an integral part of the regulatory mechanism. As a result, exon sequences are evolutionarily constrained by the need to ensure their own splicing via retention of appropriate enhancers and silencers.

3. Trans-acting splicing factors

A major paradigm in pre-mRNA splicing regulation is the concept that splicing is controlled by mutually antagonistic splicing factor proteins that bind to enhancer and silencer elements in pre-mRNA, in order to control recruitment of the spliceosomes. Typically, these proteins fall into two classes, the heterogeneous nuclear ribonucleoprotein (hnRNP) proteins, and the SR proteins characterized by domains rich in arginine and serine. Splicing activator proteins typically act as spliceosome recruiting proteins by binding to regulatory site(s) in or near an alternative exon (via a consensus RNA binding motif), and to a component(s) of the spliceosome (via a protein interaction domain). Interestingly, recruitment itself can involve any one of several different adaptors interacting with distinct spliceosomal proteins, a flexibility that may enable a cell to switch on specific sets of alternative exons in response to specific environmental signals. Equally important to splicing regulation are splicing silencer proteins that can interfere with spliceosome recruitment by blocking activity of the positive regulators. This interplay between splicing activators and inhibitors, termed "dynamic antagonism" (Charlet *et al*., 2002), plays a critical role in regulating cell type–specific splicing.

4. Alternative splicing and normal development

Implementation of alternative splicing switches during differentiation and development requires signaling mechanisms to transduce extracellular stimuli into changes in expression or activity of splicing activators and inhibitors. Alternative splicing switches can be signaled by insulin, stress hormones, or antigen treatment (Stamm, 2002), and may ultimately be mediated by tissue-restricted expression of a splicing regulatory protein, or by physiological changes in expression of a widely expressed factor (e.g., Hou *et al*., 2002; Jensen *et al*., 2000; Ladd *et al*., 2001). However, at present these mechanisms are poorly understood.

5. Alternative splicing and human disease

This subject is clearly presented in a recent review (Faustino and Cooper, 2003). Mutations that alter normal splice sites or create aberrant splice sites have long been known to underlie many human diseases. More recently it has been appreciated that subtle exon mutations and distant intron mutations can also cause disease by disrupting enhancer or silencer elements. Alternatively, disturbances in the splicing machinery itself, whether engineered in mouse models or occurring naturally in human disease states, have been shown to affect splicing patterns of many genes and cause global disturbances of cellular metabolism. Quantitative shifts in the relative concentrations of enhancer and silencer proteins could alter splice site selection of key growth regulatory genes, DNA repair functions, or apoptosis genes, and contribute to cancer progression. Many individual reports of altered splicing in cancer, and two broad bioinformatic surveys of cancer-associated splicing defects, have been published recently (Wang *et al*., 2003; Xu and Lee, 2003).

6. Future perspectives

This is an exciting time in the alternative splicing field, as new approaches offer great promise for a better understanding of the extent of alternative splicing in the human genome and better knowledge of the mechanisms by which alternative splicing is regulated. Advances in genome-wide sequence analysis and microarray technologies offer opportunities to deduce global patterns of alternative splicing in normal tissues (Johnson *et al*., 2003). This will provide a more detailed and perhaps more accurate view of splicing than what is available today from studies that are often derived from transformed cell lines or tumors that may exhibit aberrant splicing compared to normal differentiated cells. Although computational analysis of splicing regulatory elements has already begun (Brudno *et al*., 2001; Cartegni *et al*., 2003b; Fairbrother *et al*., 2002), improved methods should increase our ability to mine this sequence data for splicing regulatory signals. Together with new biochemical and genetic methods for identifying the targets of splicing regulator proteins, these advances should ultimately lead to a map of the splicing regulatory networks that control alternative splicing. Finally, the next several years should

see significant progress in understanding splicing aberrations in human disease and, more importantly, in the development of exciting new potential therapies for the correction of such splicing defects (Cartegni and Krainer, 2003a; Sazani and Kole, 2003).

Short Specialist Review

Exonic splicing enhancers and exonic splicing silencers

Stephen M. Mount
University of Maryland, College Park, MD, USA

1. Signals affecting the splicing of messenger RNA precursors

RNA splicing (*see* Article 30, **Alternative splicing: conservation and function**, Volume 3) is the process by which some sections of a primary RNA transcript (the introns) are removed, and those sections that are retained (the exons) are joined together. Splicing is carried out by the spliceosome, a large macromolecular machine consisting of five spliceosomal RNAs (U1, U2, U4, U5, and U6) and perhaps as many as 100 proteins. The assembly of a spliceosome on the pair of splice sites flanking an intron involves the recognition of splicing signals in the messenger RNA precursor (pre-mRNA) by splicing factors. Any element in the DNA sequence of a gene that helps to specify the accurate splicing of its primary RNA transcript to generate the mature RNA product is a splicing signal. In the case of genes encoding proteins, splicing signals are at the splice sites themselves and in the exons and introns flanking splice sites. Splicing signals that promote splicing and lie within exons are known as exonic splicing enhancers (ESEs), while signals within exons that repress splicing are known as exonic splicing silencers (ESSs).

5′ splice sites (those at the 5′ boundary of an intron) are generally similar to each other at the last three exon nucleotides and the first seven intron nucleotides, so that the sequence spanning the splice site resembles MAG|**GT**RAGTA (where M indicates A or C and R indicates A or G; the Ts here would be U in the RNA sequence). The underlined GT dinucleotide is invariant, or nearly so. This consensus is complementary to the 5′ end of the U1 small nuclear RNA, which is a component of the U1 snRNP (small nuclear ribonucleoprotein). Although recognition of 5′ splice sites during the initial stages of splicing is primarily accomplished by the U1 snRNP, it does not act in isolation. Not all sites bound by the U1 snRNP are ultimately used as 5′ splice sites. Factors bound to other sites on the pre-mRNA, some of which are discussed below, can promote binding between U1 snRNP and the 5′ splice site or can facilitate progression along the pathway toward splicing. Furthermore, the 5′ splice site is later "examined" by additional factors in the course of splicing. One such factor is U6 snRNA, which displaces U1 prior to the first catalytic step, and remains associated with the 5′ splice site throughout the

remainder of the splicing reaction. In general, initial selection of the 5′ splice site by the U1 snRNP is influenced by other factors, and must be followed by appropriate interactions between the 5′ splice site and other components of the spliceosome.

The 3′ splice site usually occurs immediately 3′ of the trinucleotide C**AG** or U**AG** (and occasionally AAG, but almost never GAG). In addition, there is some conservation of the first nucleotide of the exon adjacent to the 3′ splice site, bringing the number of conserved 3′ splice site nucleotides to four (Y**AG**|G, where Y is C or U and the underlined AG dinucleotide is invariant, or nearly so). How is it possible for the 3′ splice site to be specified by so few nucleotides? The answer to this question lies in the sequence immediately upstream of the 3′ splice site. Additional signals here include the branch site, which is the site where the 5′ end of the intron is joined to the intron via an unusual 2′5′ phosphodiester bond in the first step of splicing. The branch site is typically 16 to 45 nucleotides upstream of the 3′ splice site. The branch site is first recognized by a protein known as SF1 and later associates with U2 snRNA. The region between the branch site and the 3′ splice site is bound by the large subunit of U2AF (U2 auxiliary factor), a dimeric protein that later recruits the U2 snRNP to the branchpoint immediately upstream. The small subunit of U2AF binds to the 3′ splice site itself. As with the U1 snRNP, recruitment of U2AF by other factors plays an important role in the selection of splice sites. All of these factors are highly conserved among eukaryotes, but there are considerable differences among species with regard to the extent to which different components of the multipart 3′ splice site signal are conserved.

2. Exonic splicing enhancers

Auxiliary signals that are distinct from the core splice site signals described above also influence the outcome of pre-mRNA splicing. Prominent among these are ESEs, sequences in flanking exons that are required for splicing to occur, either in vivo or in vitro. Although such splicing enhancers have been identified in both exons and introns, ESEs are generally better characterized, and are probably more common. ESEs activate nearby splice sites (both 5′ and 3′ splice sites) and promote the inclusion (vs. skipping) of exons in which they reside. Initially, ESEs were recognized as purine-rich motifs containing repeated GAR (GAA or GAG) trinucleotides. However, many other sequences have now been shown to have enhancer activity (see Zheng, 2004 for review). A small number of well-defined enhancer-dependent splicing events (notably the IgM M2 exon and the female-specific exon of the *Drosophila melanogaster* doublesex gene) have been used by researchers in the field to define and characterize numerous splicing enhancers, and this approach is validated by the general observation that an ESE in one assay is typically active in others.

Many ESEs are bound and activated by one or more of several related splicing factors known as SR proteins (Graveley, 2000; Cartegni *et al*., 2002). SR proteins contain either one or two RNA-binding domains and “RS” domains that are characterized by numerous arginine-serine dipeptide repeats. SR proteins are not only essential for splicing but also for each of the first three recognizable steps of spliceosome assembly. In vitro, any one of the several SR proteins can restore splicing to a splicing extract lacking SR proteins. Thus, the essential functions of

individual SR proteins in splicing are at least partially redundant. However, there is considerable specificity to the activation of splicing by SR proteins through ESEs. Individual SR proteins differ with respect to the sequence-specificity of their RNA-binding domains, and with respect to their ability to recognize and activate different ESE sequences (e.g., Liu *et al*., 1998).

The relationship between sequence-specific binding by SR proteins and the activation of splicing by ESEs is complex and incompletely understood. Both restoration of splicing and activation of some enhancer-dependent splicing events by an SR protein lacking the RS domain have been reported (Zhu and Krainer, 2000). Conversely, recruitment of the RS domain of SR proteins to an RNA by means of an unrelated RNA-binding domain is sufficient to activate enhancer-dependent splicing events, implying that the role of ESEs is to recruit such an activation domain (Graveley and Maniatis, 1998). Although only a few dozen splicing events have been shown to be enhancer dependent, the existence of ESEs within constitutively spliced exons (e.g., Schaal and Maniatis, 1999) suggests that ESEs are ubiquitous, redundant, and required for all splicing events. This possibility is supported by the observation that RNA-binding activity is required in order for an SR protein to support splicing in vitro. Recent evidence that SR proteins function in mRNA export (Huang *et al*., 2004) and nonsense-mediated decay (Zhang and Krainer, 2004) suggests that ESEs may play a role in these processes as well.

3. Exonic splicing silencers

Sequences in exons that act to suppress local splicing events are known as exonic splicing silencers or ESSs. Although ESSs are less well characterized than ESEs, they may be just as important in overall splice site selection, particularly in suppressing the inclusion of pseudoexons (regions within long introns that might otherwise be incorporated into mRNA as an exon (Sun and Chasin, 2000)). In many cases, ESSs are known to be bound by hnRNP proteins (particularly hnRNP A, hnRNP H, or hnRNP I, which is also known as PTB, pyrimidine-tract binding protein), but it appears likely that the basis of ESS activity is more variable than ESE activity. In theory, an ESS (acting through whatever protein or proteins recognize it) can act either by blocking the action of one or more ESEs or by directly blocking the activation of nearby splice sites.

4. Identification of ESEs and ESSs

It appears likely that many sequences can act as splicing enhancers or silencers, and it is estimated that as many as 15–20% of random sequences 20-nt long contain a splicing enhancer (Blencowe, 2000). Originally, ESEs were identified when mutational analysis of genes revealed that sequences within exons were required for proper splicing. Significantly more sequences were found when high-throughput selections for short sequences that might act as enhancers were carried out, either in vitro (e.g., Liu *et al*., 1998) or in vivo (e.g., Coulter *et al*., 1997). The most definitive assays of this type have been carried out with extracts dependent

upon a single purified SR protein (Liu *et al*., 1998). Because these ESE assays depend on recovering the ESE as part of a spliced RNA, experimental identification of ESSs, which are not part of the spliced RNA, has lagged behind, but was recently accomplished by Wang *et al*. (2004) using a cell-sorting assay.

Methods for the computational identification of ESEs and ESSs are generally based on some measure of oligonucleotide frequency. Indeed, content-based measures for detection of coding sequence used in many genefinders (*see* Article 14, **Eukaryotic gene finding**, Volume 7 and Article 16, **Searching for genes and biologically related signals in DNA sequences**, Volume 7) (Zhang, 2002) are likely to reflect frame-independent preferences (Antezana and Kreitman, 1999), including ESEs and (the absence of) ESSs. Gibbs sampler techniques have been used to identify ESE motifs within experimental data (Liu *et al*., 1998) and are the basis of the SEE-ESE web server (**http://www.tigr.org/software/SeeEse/eseF.html**). A bivariate statistical analysis that requires both overrepresentation in constitutive exons relative to introns and overrepresentation in exons that lack strong splicing signals (RESCUE-ESE, Fairbrother *et al*., 2002) was successful in identifying hexamers whose activity was later verified experimentally and through patterns of conservation (Fairbrother *et al*., 2004a). Direct use of conservation at synonymous sites has proven useful for predicting experimentally verified ESEs in Arabidopsis (Pertea, Salzberg and Mount, in preparation). Zhang and Chasin (2004) identified ESS motifs by comparing the frequency of 8-mers in internal noncoding exons versus unspliced pseudoexons, and similar motifs were identified by the high-throughput experimental screens of Wang *et al*. (2004).

5. ESEs and ESSs in genetic disease

Web servers are available for the identification of potential animal ESEs based on in vitro selection (Cartegni *et al*., 2003) or RESCUE-ESE (Fairbrother *et al*., 2004b) and for Arabidopsis ESEs (SEE-ESE, Pertea, Salzberg and Mount, in preparation). In part due to these web servers, there is an increased recognition in recent years that mutations in ESEs can be responsible for genetic disease. As a result, there has also been an explosive growth (since 2000) in the number of papers that describe mutations that inactivate an ESE.

Short Specialist Review

Gene finding using multiple related species: a classification approach

Manolis Kellis

MIT Broad Institute for Biomedical Research, Cambridge, MA, USA

1. Introduction

Ideally, we should be able to systematically discover all the functional genes in a newly sequenced genome from its sequence alone. Computational discovery methods rely both on the direct signals used by the cell to guide transcription, splicing, and translation, and also on indirect signals such as evolutionary conservation. In this paper, we summarize the principles of a classification-based approach for systematic gene identification, on the basis of comparative sequence information from multiple, closely related species. We first frame gene identification as a classification problem of distinguishing real genes from spurious gene predictions. We then present the Reading Frame Conservation (RFC) test, a new computational method implementing such a classification approach, on the basis of the patterns of nucleotide changes in the alignment of orthologous regions. We finally summarize our results of applying this method to reannotate the yeast genome, and the challenges of using related methods to discover all functional genes in the human genome.

2. Defining real genes

What is a real gene? This question is relatively easy to answer for those genes that are abundantly expressed, encode well-characterized proteins, and whose disruption affects a specific function in the organism. Beyond these, the distinction is much more subtle between functional genes and spurious gene predictions.

Experimentally, the definition of a functional gene comes largely as accumulating evidence of its usage, including gene expression (Velculescu, 1997), protein fragments (Rezaul *et al*., 2005), biochemical function (Jackman *et al*., 2003), protein interactions (Bai and Elledge, 1997), or the effect of its disruption (McAlister and Holland, 1982). It is important to note, however, that absence of experimental evidence does not imply that a gene annotation is spurious: a real

gene may be missing experimental evidence because it is not used in the particular conditions surveyed. Conversely, any individual report of gene usage could be due to experimental noise, cross-hybridization, or chance transcription events due to a basal level of intergenic transcription. Thus, experimental evidence alone is insufficient to distinguish between real genes and spurious gene predictions.

Computationally, the processes of transcription, splicing, and translation can be thought of as a series of decisions taken by the cell, based on signals in the genome. These signals include distant enhancer elements, regulatory elements surrounding the transcription start site, splicing enhancer and repressor signals in the message, and translation signals in the sequence or structure of mature mRNAs (Fairbrother *et al*., 2002; Wang, 2004; Thanaraj and Robinson, 2000; Yeo and Burge, 2004). The subset of these signals that we currently understand is insufficient to specify the set of known genes. Thus, in addition to the *direct* signals used by the cell, gene identification methods (Burge and Karlin, 1997; Majoros *et al*., 2004; Kulp *et al*., 1996; Krogh, 1997; Henderson *et al*., 1997; Stanke and Waack, 2003; Salzberg *et al*., 1998) routinely identify genes using additional *indirect* signals (reviewed in Fickett and Tung, 1992), which are not available to the cell, although they are generally good indicators of protein-coding genes. These include the frequency of each codon in protein-coding regions, the overall length of the translated protein product, and importantly, the evolutionary conservation of protein sequences across related species.

Evolutionary conservation is perhaps the strongest indicator that a predicted gene is functional. A gene that confers even a slight evolutionary advantage can be conserved across millions of years, regardless of the rarity of its usage. Hence, even if experimental methods fail to detect the usage of a gene in a given set of experimental conditions, evolutionary methods are able to detect *indirect* evidence of its usage, by observing the pressure to preserve its function over millions of years.

3. Gene finding as a classification problem

The challenge of using evolutionary conservation to define genes lies in the ability to reject spurious genes. Although it is generally well understood that genes conserved across large evolutionary distances are functional, lack of conservation is generally attributed to evolutionary divergence, thus providing no evidence toward either accepting or rejecting a gene prediction.

Yet, the comparison of related genomes contains information much richer than simply the presence or absence of a protein in a genome. By working with closely related genomes, we can define regions of conserved gene order, or *synteny blocks*, which span several genes, and potentially entire chromosomes. Defining conserved synteny blocks allows us to construct global alignments, spanning both well-conserved regions and regions of low conservation. In particular, these give us access to full nucleotide alignments for all predicted genes and for all intergenic regions within orthologous segments.

With the availability of orthologous alignments for both protein-coding and noncoding regions, we can study their distinct properties and build a classifier between the two types of region. The simplest and most commonly used such classifier

observes the overall level of nucleotide conservation in the alignment, and selects regions of high conservation that are likely to be functional. Other classifiers may observe more subtle signals, such as the number of amino acid changes per nucleotide substitution (Hurst, 2002), the frequency of insertions and deletions, the periodicity of mutations, and so on. By working with properties of the nucleotide alignment, rather than protein alignment, we are able to apply it uniformly to evaluate both genes and intergenic regions in the same test.

One particular conservation property unique to protein-coding segments is the pressure to preserve the reading frame of translation. Since protein sequences are translated every three nucleotides, the length of insertions and deletions (indels) is largely constrained to remain a multiple of three, thus preserving the frame of translation. Within coding regions, indels that disrupt the frame of translation are excluded, or compensated with nearby indels that restore the reading frame. In noncoding regions, the length of indels does not have this constraint, and short spacing changes are tolerated.

To evaluate this property quantitatively, we developed the RFC test. This test evaluates the pressure to preserve the reading frame in a fully aligned interval, by measuring the portion of nucleotides in this interval for which the reading frame has been locally conserved (Kellis *et al*., 2004). The RFC test provides a classifier between coding and noncoding regions that is completely independent of the traditional signals used in gene identification. It does not rely on start, stop, or splicing signals, nor does it rely on the conservation of protein sequence. It can, therefore, be combined with existing gene-finding tools and provide a highly informative score for any interval considered.

4. Reannotation of yeast

A classification approach is particularly well suited for the yeast genome. The general scarcity of introns makes it hard to rely on splicing signals to discover genes. Thus, the annotation of *Saccharomyces cerevisiae* has traditionally relied solely on the length of predicted proteins to annotate genes, resulting in 6062 annotated open reading frames (ORFs), which potentially encode proteins of at least 100 amino acids (aa). Additionally, a tentative functional annotation has been inferred for as many as 3966 of these ORFs, on the basis of classical genetic experiments and systematic genome-wide studies of gene expression, deletion phenotype, and protein–protein interaction. Together, the interval-based annotation and the large set of well-known genes make it possible to apply the RFC test systematically to evaluate the functional significance of the remaining ORFs.

To apply the test, we constructed multiple sequence alignments for every ORF and every intergenic region across four closely related species. We sequenced and assembled the genomes of *S. paradoxus*, *S. mikatae*, *and S. bayanus* (Kellis *et al*., 2003), and defined genome-wide synteny blocks with *S. cerevisiae*, on the basis of discrete anchors provided by unique protein blast hits (Kellis *et al*., 2004). Within these synteny blocks, we constructed global alignments of orthologous genes and intergenic regions across the four species using CLUSTALW (Higgins and Sharp, 1988), and systematically evaluated each alignment. We compared *S. cerevisiae* to

each species in turn, and every comparison cast a vote based on its overall RFC and a species-specific cutoff. A decision was then reached for each gene by tallying the votes from all comparisons.

We evaluated the sensitivity and specificity of the approach based on the 3966 genes with functional annotations ("known genes"), and 340 randomly chosen intergenic sequences with lengths similar to the annotated ORFs. The RFC test correctly accepted 3951 known genes (99.6%) and rejected only 15 known genes; upon manual inspection, these 15 are indeed likely to be spurious (most lack experimental evidence, and deletion phenotypes of the rest are likely due to their overlap with the promoter of other known genes). The method also correctly rejected 326 intergenic regions (96%), accepting only 14 intergenic regions (of which 10 appear to define short ORFs or extend annotated ORFs, suggesting that at most 1% of true intergenic regions failed to be rejected by the RFC test). In summary, the RFC test shows a very strong discrimination between genes and intergenic regions, with sensitivity and specificity values greater than 99%.

We then applied the RFC test to all previously annotated genes, leading to a major revisiting of the yeast gene set. For ORFs with lengths greater than 100 aa, our analysis accepted 5538 ORFs and rejected 503 (of which 376 were immediately rejected, 105 were rejected with additional criteria, and 32 were merged with neighboring ORFs); the classifier abstained from making a decision in 20 cases. The rejected ORFs show an abundance of frame-shifting indels across their entire length, in-frame stop codons, and low conservation of protein sequence, in addition to the low RFC score; their length distribution and atypical codon usage additionally suggest that they are likely occurring by chance (Goffeau, 1996; Dujon, 1994; Sharp and Li, 1987); furthermore, previous systematic experimentation showed no compelling evidence that these may encode a functional gene. Thus, it appears that more than 500 previously annotated ORFs in the yeast genome are spurious predictions.

Below the 100 amino acid cutoff, no previous systematic annotation or experimentation was available. Thus, to validate our method, we compared the results of the RFC test with an independent metric: the proportion of the *S. cerevisiae* ORF that was also free of stop codons in the other three species. Between 50 and 99 aa, we found that the method is still reliable and reports 43 candidate new genes at that length. As ORFs smaller than 50 aa were tested, we found that the specificity of the test decreased, since small intervals tend to be devoid of indels by chance rather than by presence of selective pressure. Thus, additional constraints, and additional species, will be needed to discover genes reliably at such short lengths.

In addition to the discovery of genes themselves, the comparative analysis allowed us to refine gene boundaries. Once an interval was determined to be under selective pressure for RFC, the boundaries of that interval were adjusted on the basis of the conservation of start/stop/splice signals and the boundaries over which the reading frame is conserved. This led to a large-scale reannotation of gene structure, which affected hundreds of genes (146 start codon changes, 67 intron changes, 32 merges of consecutive ORFs, and 45 changes of ORF ends). It is worth noting that in 134 cases, the inferred boundary changes pinpointed sequencing errors in the primary sequence of *S. cerevisiae*, ~50 of which were tested and

corrected by resequencing. These boundary changes reveal the true location of promoter regions, new protein domains in elongated ORFs, and previously overlooked functional relationships in the case of merged ORFs

In summary, the RFC test was able to reliably distinguish between genes and intergenic regions, leading to a systematic reannotation of the yeast genome. The comparative analysis led to the rejection of more than 500 previously annotated genes, and to the discovery of many novel genes. The results agree with similar comparative analyses carried out from a number of yeast species (Cliften *et al*., 2003; Blandin, 2000; Wood *et al*., 2001; Brachat, 2003). In addition, it allowed us to refine the gene structure of hundreds of genes, adjusting start and stop boundaries, merging consecutive ORFs, and discovering many new introns. Moreover, by using multiple species, the signals leading to gene identification were powerful enough to pinpoint sequencing errors in any individual species, including *S. cerevisiae*.

5. Implications for the human genome

The challenge of gene finding in the human genome is far greater than in yeast, due to the vastly larger intergenic regions, numerous and large introns, small exons, and alternatively spliced genes. Most approaches to gene finding in higher eukaryotes have relied on Hidden Markov Models (Burge and Karlin, 1997; Majoros *et al*., 2004; Kulp *et al*., 1996; Krogh, 1997; Henderson *et al*., 1997; Stanke and Waack, 2003), which inherently emphasize the importance of exon chaining and rely on knowledge of the expected length distributions for both exons and introns. These have been recently extended to use sequences from multiple species (Yeh *et al*., 2001; Siepel and Haussler, 2004a; Siepel and Haussler, 2004b; Batzoglou *et al*., 2000; Korf *et al*., 2001; Dewey *et al*., 2004; Rinner and Morgenstern, 2002; Parra, 2003; Meyer and Durbin, 2002; Novichkov *et al*., 2001). These approaches have limitations however, in cases of alternative splicing (Brett, 2000; Mironov *et al*., 1999; Cawley and Pachter, 2003), differences in splicing between species (Nurtdinov *et al*., 2003), widely varying exon and intron lengths, and noncanonical splice sites.

An exon-based classification approach to gene finding can help overcome these limitations. By exhaustively enumerating and testing all candidate protein-coding intervals, classification approaches make exon detection independent of chaining. Splice site models can be applied to each species independently and then compared with each other, which is much stronger than the evidence in any one species alone. The intervals can be then tested on the basis of discriminating variables that distinguish genes from noncoding regions (Fickett and Tung, 1992; Goldman and Yang, 1994). New discriminating variables can be defined as alignments of each type of region are systematically compared, and these can be combined and weighted, leveraging traditional machine-learning techniques for feature selection and classification (Moore and Lake, 2003). Once relevant intervals have been identified, their boundaries can be adjusted for optimal chaining into complete genes. In particular, chaining can also leverage an inferred frame of translation for each exon, based on the higher mutation rate observed in largely degenerate third codon positions (Hurst, 2002). The exon-chaining step produces full gene models,

and is able to cope with alternative splicing and missing exons, since it is not constrained to a single optimal path through the exons.

By systematically observing alignment properties of large sequence regions, we can build new rigorous approaches for sequence analysis. These are widely applicable beyond coding exons, and similar classification-based approaches can be used to distinguish CpG islands, 5′- and 3′-untranslated regions, promoter regions, regulatory islands, and other functional elements. Through the lens of evolutionary selection, our ability to directly interpret genomes is revolutionized. Coupled with systematic experimentation and validation, these analyses can lead to a systematic catalog of functional elements in the human genome, forming the future foundations of biomedical research.

Dynamic programming for gene finders

William H. Majoros
The Institute for Genomic Research, Rockville, MD, USA

1. Introduction

Dynamic programming (DP), a technique commonly used in bioinformatics algorithms to reduce the evaluation time for recurrence relations, is especially prevalent in the implementation of gene-finding software. The task of gene finding has traditionally been formulated as that of choosing a single *parse*, or collection of zero or more nonoverlapping gene models, of a sequence such that the chosen parse maximizes some objective function. In general, the number of such parses can grow exponentially with the length of the sequence, owing to the combinatorial nature of the parses – that is, n nonoverlapping and frame-consistent exons can, in theory, be combined independently to produce 2^n different gene models. Thus, the explicit enumeration and evaluation of all possible parses of a sequence is generally too computationally expensive to be undertaken in practice. However, many of the objective functions favored by practitioners, particularly those that are probabilistic, can be expressed as a recurrence relation in which the value of a parse is defined recursively in terms of the values of subparses. It is this class of formulations that are amenable to dynamic programming, or DP.

There are two main approaches to DP: *bottom-up* and *top-down*. The latter, also called *memoization*, simply caches the value returned by a recursive call the first time it is made, so that subsequent calls with the same parameters can retrieve the value from the cache rather than recomputing it from scratch. By contrast, the bottom-up approach, which is more commonly used in gene finding and is slightly more efficient, involves the proactive computation of simpler subproblems before they are explicitly needed for the evaluation of more complex subproblems. The values of these subproblems are stored in an array or matrix, with the evaluation order of the cells in the matrix being determined by the recursive structure of the recurrence relation. Once the matrix has been evaluated, the optimal value can be extracted from the appropriate cell in the matrix, and the corresponding optimal solution can be obtained by tracing back through the recurrence links that were used to compute the value of each cell (assuming such links were explicitly stored or can be reconstructed during trace-back) (Cormen *et al*., 2001; Durbin *et al*., 1998).

Thus, the main tasks in devising a DP implementation of a new gene-finding strategy are (1) to formulate the objective function as a recurrence relation, (2) to map the recursive structure of that recurrence relation to the elements of a multidimensional matrix, and (3) to determine the evaluation order of the cells in that matrix. Optimization of the objective function is then achieved by evaluating all the cells of the DP matrix and then identifying the optimal cell.

2. Example uses

Examples of the actual use of DP for gene finding are legion, particularly in Markovian systems. It is standard to employ DP in both the training and application of Hidden Markov Models (HMMs) (*see* Article 98, **Hidden Markov models and neural networks**, Volume 8). The Forward, Backward, and Baum–Welch algorithms for training an HMM involve matrices wherein each cell corresponds to a conditional or joint probability on sequences and their emission by particular states. The Viterbi decoding algorithm for parsing a sequence with an HMM likewise involves a matrix with cells denoting conditionally optimal paths through the states of the HMM and their corresponding conditional probabilities. The global optimum is identified by the cell that pairs the HMM's designated final state with the end of the sequence (Durbin *et al*., 1998).

Other uses of DP for gene finding include the decoding algorithms used in applying Generalized Hidden Markov Models (GHMMs) and Nonstationary Markov Chains, and the procedures used to train and apply neural networks (Xu and Uberbacher, 1998; Rumelhart *et al*., 1986).

3. Practical considerations

Various practical considerations can complicate the task of devising and implementing a DP algorithm. Among the most prominent are those involving space/speed trade-offs. The space requirements of multidimensional DP matrices can grow very quickly as the lengths of the dimensions increase, but often it is possible to eliminate portions of the matrix from consideration right at the outset, thereby permitting the adoption of a "sparse matrix" representation in which memory is allocated only for the portions of the matrix actually needed. Such a representation may or may not improve speed and memory efficiency, but it can also require significantly more effort during the development and maintenance of the software.

Even if the complete matrix is fully allocated in memory, it may still be advantageous to eliminate from consideration certain cells in the matrix that are unlikely to contribute to the optimal solution, similar to "banded" alignment techniques. When the probabilities of these eliminated cells are small but nonzero, the resulting procedure becomes a heuristic that is no longer guaranteed to find the optimal solution. In many cases this might be acceptable, but doing this typically involves empirical studies to establish an acceptable range of values for the cells being eliminated. This may need to be done every time the gene finder is trained for a new organism.

Devising the original recurrence relations can itself be a difficult task (Sankoff, 2000). For any given set of proposed equations, a worthwhile exercise is the derivation of a rigorous proof that the equations exhibit the intended semantics and do not permit greedy behavior. Unintended greediness could allow the algorithm to maximize the objective function as encoded without strictly adhering to the intended semantics, and could thereby compromise prediction accuracy. For example, failure to properly separate the inductive scores of the three coding phases until the end of a CDS in a Markov chain promotes greedy behavior, because the phase is not selected in a globally optimal manner (Wu, 1996; Salzberg, 1998).

Validation of the final software implementation is important as well, but can be very difficult when the expected predictions of a given DP formulation are not precisely known and would be impractical to produce manually. In these cases, subtle programming errors can go undetected unless one undertakes the time-consuming exercise of rigorously tracing through a number of sample computations to verify correct operation (Geigerich, 2000).

Another complication that not uncommonly arises in DP implementations applied to long sequences is the occurrence of *numerical underflow*, in which a value in the computation becomes so small that it cannot be represented by the host machine, thereby causing a *floating-point exception* or simply rendering gene models indistinguishable by assigning them all a score of zero. This is especially common in probabilistic formulations involving the multiplication of large numbers of probabilities. Several methods for avoiding underflow have been devised, such as arbitrarily rescaling the numbers or applying the log transformation, but some of these methods, such as rescaling, can significantly complicate the implementation and validation of the program, and generally must be derived anew for each gene finder (Durbin *et al*., 1998).

In an attempt to counter some of these obstacles, several recent works have attempted to provide tools for the automatic construction of DP algorithms and software, though whether these techniques will see widespread adoption and tangibly impact the field remains to be seen (Geigerich, 2000; Birney and Durbin, 1997).

4. Future challenges

Gene-finding researchers now face an array of challenges for which new DP algorithms need to be developed. As more genomic information becomes available, the successful migration of gene-finding techniques into the realm of comparative genomics becomes increasingly important. The use of models such as Pair HMMs (*see* Article 17, **Pair hidden Markov models**, Volume 7) for gene finding entails a potentially significant increase in computational complexity that must be addressed. Recent attempts at using these models have drawn on techniques such as the use of sparse matrices, heuristic optimization, and approximate alignments (themselves relying on DP methods), and generally have involved one or more simplifying assumptions, such as strict conservation of intron/exon structure (Ureta-Vidal *et al*., 2003).

Much current work now focuses on gene prediction in two species simultaneously; generalizing this to three or more species will require yet additional

innovation to handle the enormous computational load. More generally, one might imagine more flexible DP frameworks in which suboptimal parses are made available in an efficient manner for perusal "on demand" by human annotators or for automatic integration with external evidence, perhaps in the context of a tightly coupled ensemble of separate gene-finding programs.

One possible avenue for future progress is in the parallelization of DP algorithms to enable their deployment on multiprocessing hardware. This in itself represents a considerable challenge, as many DP algorithms are inherently difficult to parallelize, due to pervasive dependencies in the recurrence structure.

Basic Techniques and Approaches

Gene structure prediction by genomic sequence alignment

Burkhard Morgenstern
University of Göttingen, Göttingen, Germany

1. Introduction

Gene prediction is the first and most fundamental step to genome analysis and annotation (*see* Article 13, **Prokaryotic gene identification *in silico***, Volume 7, Article 14, **Eukaryotic gene finding**, Volume 7, Article 21, **Gene structure prediction in plant genomes**, Volume 7, and Article 26, **Dynamic programming for gene finders**, Volume 7). Consequently, the development of gene-finding software continues to be an important area of research in Bioinformatics. Gene-structure prediction is particularly challenging for eukaryotes, in which the density of genes is low and most genes consist of multiple exons separated by introns of varying length; see Guigó (2004) for an overview on existing software for gene prediction in eukaryotes. During the last years, a large number of computer programs have been developed to identify genes in eukaryotic genome sequences. Recent studies show, however, that the reliability of these methods is limited. While most methods work well on small sequences with single genes, their performance decreases considerably when applied to BAC-sized sequences including multiple genes (Guigó *et al*., 2000).

Traditional gene-prediction programs rely on information derived from *known* genes. *Intrinsic* methods use statistical features such as ORF length or codon usage and try to identify splice junctions and other signals. The underlying models are trained using previously known genes from the same or a closely related organism. Traditional *extrinsic* methods work by comparing genomic sequences to EST or protein sequences.

With an ever-increasing number of completely or partially sequenced genomes, new *comparative* approaches have been proposed to predict genes and other functional elements. The idea is that functionally important parts of the genome are under selective pressure, so they are usually more conserved than nonfunctional regions where random mutations can be tolerated without affecting the fitness of the organism. Consequently, local sequence conservation among genomic sequences usually indicates biological functionality. This *phylogenetic footprinting* principle has been successfully applied to various problems such as detection of regulatory elements, and it is now generally accepted that comparative sequence analysis is a powerful and universally applicable tool for functional genomics.

Gene prediction by comparative sequence analysis means that instead of comparing a given sequence to previously *known* genes, one compares genomic sequences from evolutionarily related organisms to each other. Regions of local sequence conservation are then searched for relevant signals to identify possible exons and gene structures. Note that, in contrast to traditional approaches, comparative gene finding is possible without any previous knowledge about existing genes and their statistical composition – except for simple models of splice signals. Therefore, these new approaches are able to detect genes with unusual statistical features that can be missed by traditional methods.

2. Gene prediction using CHAOS, DIALIGN, and AGenDA

Comparative gene-finding approaches have been developed, for example, by Bafna and Huson (2000), Batzoglou *et al*. (2000), and Wiehe *et al*. (2001). At MIPS/GSF research center and at the University of Bielefeld, we developed a comparative gene finder called AGenDA (*Alignment-based Gene-Detection Algorithm*, Rinner and Morgenstern, 2002). The first step in comparative sequence analysis is to calculate an *alignment* of the sequences under study as the results of any comparative method can be only as good as the underlying alignment. For AGenDA, we used the alignment program *DIALIGN* (Morgenstern *et al*., 1996). This program integrates local and global alignment features by constructing alignments based on pairwise local homologies. In a number of recent research projects, DIALIGN has been applied to identify functional elements in genomic sequences.

In a preliminary study, we found that local homologies identified by DIALIGN in genomic sequences are highly correlated to protein-coding exons (Morgenstern *et al*., 2002); in this regard, DIALIGN proved to be superior to alternative alignment programs. However, since DIALIGN has originally been designed as a general-purpose aligner, the standard version of the program is too slow to align large genomic sequences. Thus, we implemented an *anchored-alignment* approach to speed up the alignment procedure. Here, we are using the fast database search tool CHAOS to identify local sequence similarities; these similarities are then used as prealigned *anchor points* to reduce the alignment search space and program running time for DIALIGN, as described by Brudno *et al*. (2003).

On a given pair of input sequences, for example, from human and mouse, AGenDA performs the following operations (for details, see Rinner and Morgenstern, 2002):

1. High-scoring sequence similarities identified by CHAOS and DIALIGN are *clustered* by bridging small gaps between them.
2. Conserved splice junctions and start/stop codons are identified around the cluster boundaries. For splice signals, standard matrices proposed by Salzberg (1997) are used.
3. A *candidate exon* (CE) is defined as a region of local sequence similarity bounded by conserved splice sites or start/stop codons, respectively. Note that a region of local sequence conservation can be bounded by more than one conserved splice signal, so it can give rise to multiple overlapping CEs, as

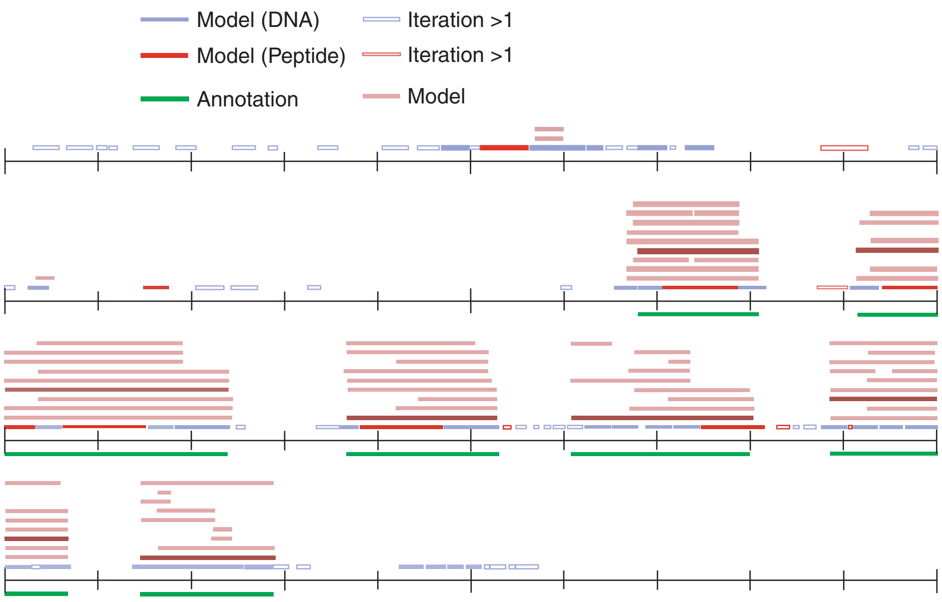

Figure 1 Gene prediction by AGenDA. A human genomic sequence of 40 kb in length has been aligned to its counterpart in the murine genome (not shown in the figure). Green lines below the sequence are known protein-coding exons. Blue and red lines above the sequence correspond to regions of local sequence similarity as identified by DIALIGN. Pink lines correspond to *candidate exons (CEs)*, that is, to local sequence similarities bounded by conserved splice sites or start/stop codons. A complete gene model is obtained as an optimal *chain* of CEs (purple lines). Local sequence conservation between human and mouse *roughly* corresponds to true exons, but is not very *specific* as many similarities outside the coding regions have been found. CEs bounded by conserved signals more accurately reflect the coding regions. Searching for optimal *chains* of CEs further reduces the noise of false-positive predictions; in our example, the optimal gene model identified by AGenDA *exactly* corresponds to the real gene

illustrated in Figure 1. Each CE is assigned a *score*, essentially depending on the level of sequence similarity and the quality of the splice signals.

4. A *candidate gene* is a chain of CEs meeting some obvious formal conditions for splice signals and start/stop codons and certain length restrictions for introns. Candidate genes are considered on the forward as well as on the reverse strand.
5. The program uses a dynamic-programming algorithm to identify a set of candidate genes with maximum total score.

3. Results and discussion

AGenDA has been evaluated on standard reference sequences from human and mouse (Batzoglou *et al*., 2000). We found that the prediction quality of AGenDA is similar to the Hidden Markov Model (HMM)-based program *GenScan* (Burge and Karlin, 1997), which is currently the most popular software tool for gene prediction in eukaryotes. It is remarkable that a method solely based on evolutionary sequence conservation yields results that are comparable to the output of sophisticated intrinsic methods. While GenScan uses species-dependent statistical models to

distinguish coding from noncoding regions, comparative methods are based on simple and universally applicable measures of local sequence similarity and on basic models for splice signals. Since these two gene-finding approaches are based on completely different types of input information, they complement each other and genes missed by one method can be detected by the other approach. A web interface for AGenDA has been set up at the Bielefeld Bioinformatics Server *BiBiServ* (Taher *et al*., 2004, **http://bibiserv.techfak.uni-bielefeld.de/agenda/**).

An obvious way of improving gene-prediction accuracy is to *combine* the predictive power of stochastical and comparative approaches. The effectiveness of such an integrated approach has been demonstrated by Korf *et al*. (2001) with their TWINSCAN program. In short, they reimplemented GenScan but also included homology information obtained from high-scoring BLAST alignments of syntenic sequences. This resulted in markedly increased sensitivity and specificity. Other combinations of intrinsic and comparative methods have been proposed by Meyer and Durbin (2002) and by Parra *et al*. (2003).

We are planning to integrate our alignment-based approach with the intrinsic gene-prediction program AUGUSTUS (Stanke and Waack, 2003). AUGUSTUS is based on a generalized HMM, with a new submodel for intron length distribution. With this new model, AUGUSTUS is superior to standard gene-finding programs if large input sequences are to be analyzed. Especially for genes with long introns, AUGUSTUS is far more accurate than other intrinsic methods. The stochastic model used by AUGUSTUS can incorporate external information in a natural way (Stanke, 2003). This way, we will use genomic alignments calculated by CHAOS and DIALIGN to further improve the performance of AUGUSTUS and to combine the advantages of these two approaches.

Acknowledgments

I would like to thank Oliver Rinner and Leila Taher for developing AGenDA, Saurabh Garg and Alexander Sczyrba for their work on the AGenDA web server, and Michael Brudno for helping us with his CHAOS software. Mario Stanke made useful comments on the manuscript.

Computational motif discovery

Martin Tompa
University of Washington, Seattle, WA, USA

Given the vast amounts of sequence data being generated by numerous genome and proteome projects, on which regions should biologists focus their attention? The goal of computational motif discovery is to predict relatively short subsequences that are good candidates to serve some biological function. This article focuses on the computational prediction of protein-binding sites in nucleotide sequences (for instance, transcription factor binding sites in DNA promoter regions) as a specific example. However, most of the ideas carry over to other applications such as predicting protein domains, splice sites, and so on.

The binding sites to be discovered are typically quite short, between 6 and 25 nucleotides in length. If one tabulated the binding sites of a single DNA-binding protein, one would find that they are not all identical because the protein typically tolerates some variation in the sequences it binds. Instead, a typical collection of binding sites for a single protein might look something like the hypothetical example shown in Figure 1, in which some positions are well conserved (for instance, C in position 2 of each binding site) and other positions less conserved (for instance, position 1).

It is this variation among binding sites that makes computational motif discovery challenging. There are many different motif "models" that can be adopted in an attempt to characterize the variation. One of the simplest such models is the *consensus string*. For instance, the eight binding sites in Figure 1 can be described as being near the consensus ACGTCGT, allowing up to two nucleotide substitutions from this consensus. A second simple motif model is the *IUPAC* description. Each of the binding sites in Figure 1 is an instance of the IUPAC string RCGWYGW, where R stands for either of the purines A or G, Y stands for either of the pyrimidines C or T, and W stands for either of the weakly binding nucleotides A or T.

Both the consensus and IUPAC motif models have the advantage that motif discovery algorithms can systematically enumerate all possible motifs, since a motif is characterized by a single consensus or IUPAC string. Along with this advantage comes a disadvantage that these models do not have the nuanced expressiveness that sometimes is needed to describe a collection of binding sites accurately. Possibly, a more realistic motif model is the *weight matrix*, sometimes called *position-specific scoring matrix*. An example of a weight matrix for the binding sites of Figure 1 is shown in Figure 2. This matrix has one column for each of the seven nucleotide positions of the binding site. Column p assigns scores to each of the nucleotides

Figure 2 Log likelihood ratio weight matrix for example of Figure 1

that might appear in position p of a binding site. The higher the total score over all seven positions, the closer a potential binding site is to the collection of binding sites in Figure 1. For instance, the aforementioned consensus string ACGTCGT has a score of $1.2 + 1.9 + 1.9 + 0.9 + 0.9 + 1.9 + 1.2 = 9.9$, the highest possible score for this matrix.

Once a motif model has been selected, the next question is the type of motif discovery application. The input nucleotide sequences might be genes from a single genome that are each suspected to contain binding sites of a single protein, perhaps collected from knockout or gene expression experiments. Alternatively, the sequences might be homologous genes, typically one each from multiple related genomes. These two applications are distinguished by the names *statistical overrepresentation* and *phylogenetic footprinting*, respectively.

In the case of statistical overrepresentation, three different types of motif discovery algorithms have proved successful. The first type is *enumerative*, using either the consensus or IUPAC motif model enumeratively as outlined above. Examples of this approach are the programs RSAT (van Helden *et al*., 2000) and YMF (Sinha and Tompa, 2002). A second type of algorithm might be described as *iterative improvement*. These typically use the weight matrix model and alternate between (1) improving the current set of binding sites, given the current weight matrix, and (2) improving the current weight matrix, given the current set of binding sites. Successful programs that use this approach are the Gibbs sampler (Lawrence *et al*., 1993) and MEME (Bailey and Elkan, 1995). The third approach also uses the weight matrix model and what computer scientists call the *greedy* method, progressively adding to the current set of binding sites that short sequence that is closest to them. This approach is exemplified by the program Consensus (Hertz and Stormo, 1999). Which of these approaches is most accurate depends to a large extent on which motif model most accurately reflects the biological sites sought.

In the case of phylogenetic footprinting, there have been two approaches used. In the traditional approach, the entire homologous sequences are first globally aligned

using a multiple alignment program such as Clustal W (Thompson *et al*., 1994) or Dialign (Morgenstern, 1999). From this global multiple alignment, one then selects short sequences of contiguous columns that show unusually high conservation, by some measure closely related to one of the motif models discussed above. The disadvantage of this approach is that, if the sequences are too diverged, the short conserved binding sites are overwhelmed by the "noise" of the surrounding random sequence, and the alignment tool, in an attempt to align all the noise well, will fail to align the desired binding sites. To avoid this problem, the program FootPrinter (Blanchette and Tompa, 2002) was designed to search directly for well conserved short motifs without resorting to global multiple alignment at all. FootPrinter uses the phylogeny relating the sequences to guide this search.

The References section provides websites, where all of these motif discovery programs are available to users.

Introductory Review

In silico approaches to functional analysis of proteins

L. Aravind

National Institutes of Health, Bethesda, MD, USA

1. Introduction

Proteins are unrivaled as the primary functional agents of all biological systems. Hence, understanding how protein sequence and structure relate to its function is tantamount to decoding the most basic aspects of any given biological system. The emergence of the genomic era has resulted in an explosive growth of available protein sequences and other forms of protein-related information. This has not only placed considerable pressure on the conventional techniques of biochemistry and molecular biology to scale up their range of operations but has also created a strong demand for theoretical prediction of biological and biochemical functions from the available data. In particular, the immense preponderance of protein sequence data over all other forms of information pertaining to proteins places a considerable premium on the need to use sequence information as the central platform for exploring the core aspects of biology. Accordingly, reconstructing protein function requires an understanding of the dependencies between the sequence of a protein, and its structure, cellular localization, interaction with functional partners, and its contributions to the fitness of the organism. Fortunately, the ever-increasing flux of data, combined with the basic principles of protein biochemistry and evolutionary biology are only improving our understanding of these dependencies and our ability to ask new questions, which were previously impossible. In this article, we shall briefly consider the founding principles required to tackle the issue of proceeding from protein sequence/structure to biological function.

2. Information in protein sequence: domain identification and function

Pioneering explorations of the protein universe by the early structural biologists resulted in the identification of an organizational level beyond the α-helix, the β-strands, and other basic elements of protein secondary structure. These higher-level structural features were characterized by the presence of independent folding units that were spatially well delineated from each other and often mapped to a collinear

stretch of sequence in the polypeptide. These units, termed *domains*, proved to be the most relevant organizational aspect of protein in terms of understanding protein function. A striking example that illustrated the domain concept in the early days was provided by the structure of the immunoglobulins (Doolittle *et al*., 1966). These proteins had a number of structurally similar domains per polypeptide, each of which was largely composed of β-strands. Comparisons of these structurally similar immunoglobulin domains revealed a similarity even at the sequence level. This suggested their origin from an ancestral sequence unit that specified a single domain, through the process of duplication followed by sequence divergence. Identification of domains also provided the first clues regarding events beyond simple mutations in the evolution of proteins, such as recombination between unrelated genes. Thus, the genesis of large, complex proteins was made more tangible by explaining it in terms of duplications and shuffling of the smaller units, namely, the domains.

Furthermore, there also appeared to be a strong correspondence between these domains and specific biochemical activities or functions of proteins that contained them. Early examples of this principle were provided by the flavin or nicotinamide dinucleotide-binding Rossmann fold domain (Rao and Rossmann, 1973) and the DNA-binding Helix-turn-Helix domain (HTH) (Matthews *et al*., 1982; Sauer *et al*., 1982). These domains were respectively identified as the structural common denominator in otherwise unrelated proteins that bound either FAD/NAD or DNA. Experimental evidence from these proteins showed that their respective substrate binding abilities were essentially dependent on the Rossmann fold or the HTH domains (Figure 1). This fairly consistent, unitary relationship between the biochemical activities of proteins and their constituent domains suggested that the delineation of domains in a polypeptide could lead to the prediction of its biochemical and biological properties. Additionally, the presence of sequence conservation corresponding to the structural similarity of the domains implied that protein sequence information could be used as the basis for these predictions (Figure 1).

From the earliest days of protein sequence comparisons, it became clear that several proteins with shared biochemical properties, such as DNA-binding, or catalytic activities, such as ATP hydrolysis or proteolysis, often shared collinear sequence patterns or motifs that correlated with a given activity (Bork and Koonin, 1996). Experimental analysis of these protein sequence motifs (PSMs) through site-directed mutagenesis, suggested that they often corresponded to the structural core of the fold, the active site, or the substrate interaction surfaces of a given protein (Bork and Koonin, 1996). Furthermore, superposition of these conserved motifs on to the three-dimensional structures of proteins, when available, showed that the motifs could also be used in defining domains in proteins through sequence analysis. While these labors strengthened the association of sequence motifs with protein domains and their biochemistry, they also emphasized the need for objective methodologies to weed out false relationships (patterns) (Iyer *et al*., 2001).

The models, such as the extreme value distribution, originally developed for pairwise ungapped local alignments obtained in similarity searches between a query protein and the target database provided the first objective means for evaluating the statistical significance of sequence alignments (Karlin and Altschul,

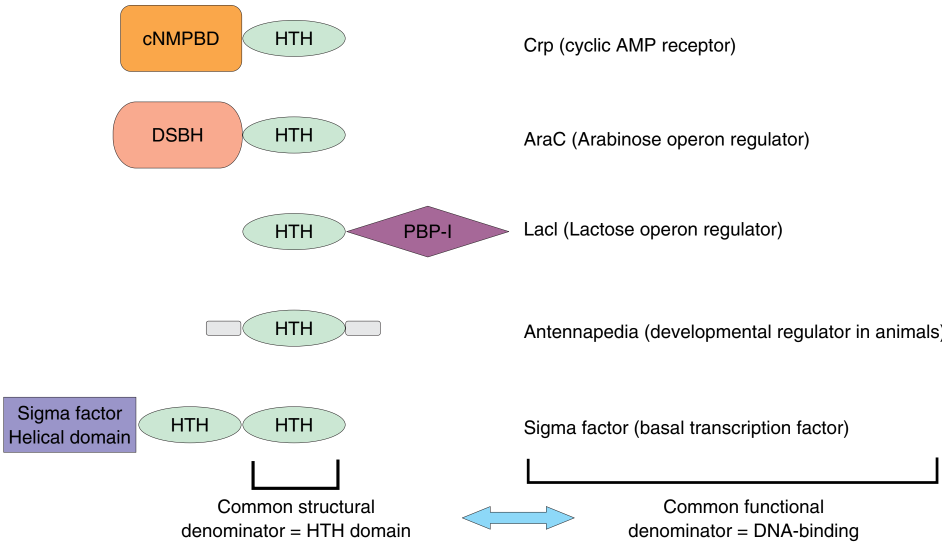

Figure 1 Correspondence between shared conserved domains and common biochemical function. Various transcription factors that share the common biochemical property of DNA binding also share a Helix-turn-Helix domain (HTH). This indicates that the correspondence between the HTH domain and DNA-binding function. The other conserved domains fused to the HTH domain are cNMPBD: the cyclic nucleotide-binding domain; DSBH: the double-stranded beta-helix domain, a sugar binding domain; PBPI: the periplasmic-binding protein I domain (also sugar binding). The grey boxes in the Antennapedia protein are the nonglobular regions

1990). Subsequently, more sensitive sequence profile methods for the detection of remote sequence similarity were developed on the basis of either position-specific score matrices (PSSM) (Altschul *et al*., 1997) or hidden Markov models (HMM) (Durbin *et al*., 1998). Simulations showed that the original extreme value model, developed for the ungapped alignments, was also valid for gapped alignments and those obtained in the sequence profile searches (Altschul *et al*., 1997). These developments enabled the robust definition of PSMs, detection of distant structural relationships and protein domains using sequence information available in the protein databases (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7 for details). Thus, with the basic procedure for the objective identification of protein domains through sequence analysis in place, the path for the in silico journey from protein sequence to function was firmly established.

The foundational principles for protein sequence analysis are deceptively straightforward, but their actual application is often bedeviled with numerous caveats, and overlying modifiers coming from other sources of information. We shall briefly consider some of these issues in the reminder of the article.

3. Sequence conservation and its functional significance

The mere detection of evolutionary (genuine) sequence similarity (termed *homology*) between two proteins does not mean that they are necessarily functionally

equivalent. For a proper evaluation of the relevance of the homology between a set of proteins, a detailed understanding of the qualitative nature of the relationship and its significance is required. A set of homologous proteins or domains are best represented as a multiple sequence alignment of the various independent occurrences of the domain or protein. The degree of relationship, defined on the basis of an objective method of sequence similarity, is typically a continuum between the extremes for any comprehensive multiple alignment of an assemblage of homologous proteins. Some copies of the domain are very similar, others more divergent, and so on, till we reach the limit of objective detection of relationships. This most inclusive set of evolutionarily related domains is defined as a *superfamily*. Natural subdivisions within the superfamily such as families and subfamilies may also be definable on the basis of sequence similarity. Typically, all members of a superfamily might share a generic biochemical property, such as catalysis of a common class of reactions or binding to a particular class of substrates. For example, members of the GNAT acetyltransferase superfamily usually catalyze the transfer of the acetyl functional group to amino groups on various substrates. The identification of the GNAT acetyltransferase domain in a protein allows prediction of such a biochemical activity in that protein, but it does not automatically specify the substrate or the actual biological role played by the protein.

In many cases two or more superfamilies may show generic similarity in terms of the topology of secondary structure elements and features of their structural arrangements, despite the absence of any detectable sequence similarity between them. These superfamilies are then described as sharing a common *fold* (Andreeva *et al*., 2004). The identification of a shared fold in different superfamilies is usually not indicative of any specific shared biochemical properties, though they might show some general commonalities in terms of the spatial position of the interaction with substrates or location of active sites. Hence, the detection of a common fold in different superfamilies by itself is usually not a good predictor of similar biochemical aspects of their function.

An understanding of the levels at which natural selection sculpts a protein helps in gleaning more specific information from a set of homologous proteins. In most proteins from a given organism, natural selection acts in the purifying sense to maintain three different levels of information in the sequence:

1. The most stringent level is the structural level – selection weeds out any changes that could destabilize the basic folding pattern of the domain. Thus, the bulk of sequence conservation, particularly patches of hydrophobic residues, metal-chelating residues, and disulfide-bond-forming cysteines, corresponds to the residues that are likely to be critical for the folding and stability of a protein. These patterns are typically preserved throughout a given superfamily of proteins.
2. At the next level of stringency, natural selection safeguards the "active sites" of proteins. In the case of enzymes, these sites are the constellation of residues required for the catalytic activity and substrate interactions, while in the case of other proteins they are other key residues required for their characteristic biochemical activities. These are less critical as compared to the structure-conferring features because two proteins descending from a common ancestor

might adopt different biochemical properties as they diverge. For example, one of the descendent proteins might be selected for its enzymatic activity and retain the catalytic residues, while the protein belonging to a sister clade descending from the same ancestor might be selected for its ligand-binding properties and would not be under any pressure to retain the catalytic residues, though both proteins are selected to retain the same structure. The identification of such residues is most critical for making meaningful prediction regarding the biochemical functions that might be shared by a group of proteins (Aravind *et al*., 2002).

3. At the lowest level in the hierarchy, natural selection preserves the features of a protein that contain information relevant to its biological context. These might include the residues necessary to interact with other proteins in the pathways or complexes in which they function. Such features are not preserved when proteins that diverge from a common ancestor adapt to different functional milieus. However, identification and characterization of such residues help in narrowing down on actual biological role of proteins to a much greater degree.

4. Low entropy and nonglobular structures in proteins

Beyond the well-defined domains that tend to form compact globular domains with regular secondary structure elements, there is an entire spectrum of low entropy structures ranging from superstructure forming repeat units to random coils. These nonglobular structures, while not following the same structure–function relationships as the globular domains, might still provide useful biological information. Amongst the most common nonglobular structures are transmembrane (TM) helices and signal peptides, which are characterized by compositionally biased regions of proteins that are highly enriched in hydrophobic residues (*see* Article 37, **Signal peptides and protein localization prediction**, Volume 7 and Article 38, **Transmembrane topology prediction**, Volume 7). Another class of nonglobular proteins includes the fibrous proteins, like keratin, which form long alpha-helical structures. This helix dimerizes with another such helix and forms a structure termed the *coiled coil*. Shorter coiled coils, also known as *leucine zippers* due to a periodic pattern of leucines, are found in a wide variety of proteins and serve as important determinants of protein dimerization (Lupas, 1996). Likewise, more complex repeats found in proteins, such as the tetratricopeptide repeat (TPR), typically organize into superhelical or propeller-like structures that serve as surfaces for interactions with other protein complexes (*see* Article 33, **Protein repeats**, Volume 7).

Yet another nonglobular segment observed in proteins is the unstructured or random-coil segment that generally does not assume a single stable configuration and occurs in solution in a highly mobile disordered state. These regions of proteins correspond to sequences with a low complexity – they are enriched in certain amino acids but lack others. In the extreme case, they might contain homopolymeric stretches of a single amino acid such as glutamine or proline, while in other cases di- or tripeptide repeats (*see* Article 32, **Sequence complexity of proteins and its significance in annotation**, Volume 7). These nonglobular regions are particularly

common in the eukaryotes, and often contain the sites for modification by a variety of enzymes such as kinases, glycosyltransferases, and NH_2-group acetyltransferases or binding sites for specific peptide-binding domains such as SH3 or WW domains (Zarrinpar *et al*., 2003). They might also contain signals for nuclear localization and other subcellular sorting signals. Given these associations, the identification of nonglobular segments often serves as a means to predict important aspects of a protein's function, such as its subcellular localization and its potential to mediate protein–protein interactions. Thus, combining the information obtained from particular low entropy regions with the biochemical insights provided by the conserved globular domains often improves the precision of functional predictions.

5. The "society" of domains and the domain-Lego principle

The structural independence of domains allows different domains to associate or dissociate from each other within a single polypeptide in the course of evolution. The majority of domains show a certain degree of "social behavior", that is, co-occurrence with other domains. As a result, a significant fraction of the globular proteins encoded by an organism are collections of domains fused together. In most cases, these domains occur successively, next to each other, or are separated from each other by short or long nonglobular segments. In a smaller number of cases, a domain might occur inserted in a loop of another domain. The order and the combination of domains found in a polypeptide is termed the *domain architecture* of the protein, and is generally schematically depicted by filled shapes standing for domains distributed along the length of the protein (Figures 1 and 2). Thus, the evolutionary process in which domains conglomerate in a protein can be likened to the construction of complex objects using simple Lego bricks (groove-bearing interlocking Danish bricks that is a recreational toy in parts of the Western hemisphere). Just as artists using a relatively limited repertoire of Lego bricks have been able to generate a remarkable diversity of forms, natural selection and recombination have fashioned an astonishing diversity of domain architectures.

Despite the variety of architectures, most of them can be grouped into a limited set of categories with specific teleological principles.

The chief architectural categories include:

1. *Solo domains*: The occurrences of a domain all by itself in a polypeptide may or may not have a definite adaptive explanation (Figure 2). It can be safely assumed that this is the basal state of any domain in evolution, and any adaptively advantageous association with another domain is likely to be fixed. Thus, domains could stochastically flip in and out of neutral combinations with other domains, but any domain that has remained solo across evolutionarily distant organisms is likely to be under certain selective pressure to remain independent.
2. *Architectures involving homodimeric or multimeric assemblies of the same domain*: Individual domains that frequently function as dimers or multimers are selected to exist in domain architectures with two or more copies of the

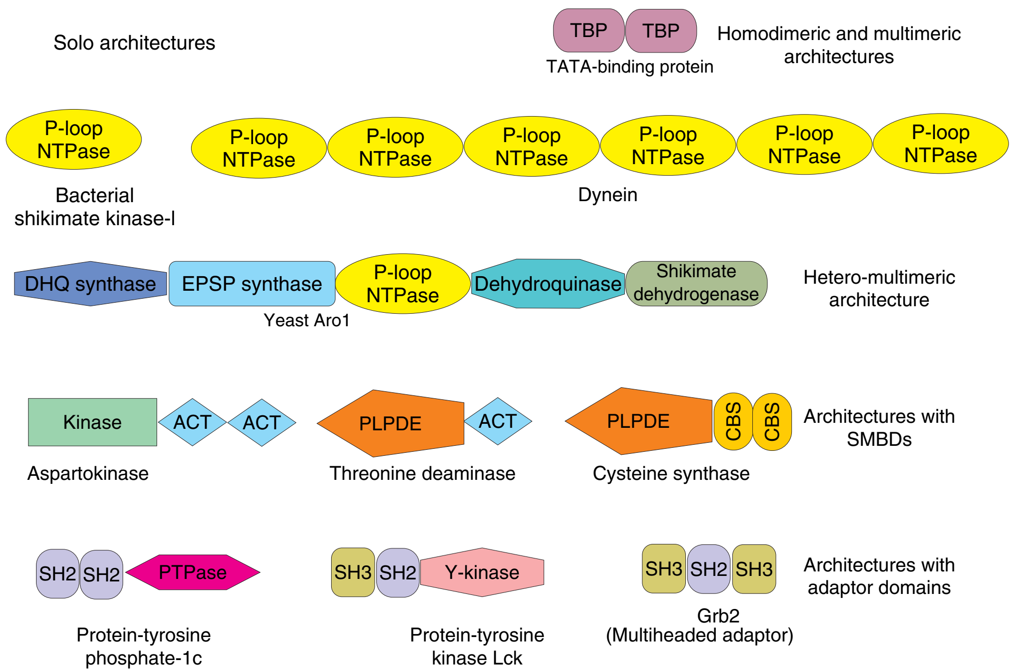

Figure 2 Categories of domain architecture. The domains depicted in the figure are P-loop NTPase: NTP utilizing catalytic domain of the P-loop fold; TBP: the DNA-binding domain of the TATA-binding proteins; DHQ synthase: 3-dehydroquinate synthase; EPSP synthase: 5-enolpyruvylshikimate-3-phosphate; ACT: a small molecule–binding domain; CBS: the so-called cystathionine beta synthase domains (also small molecule–binding domains); SH2: an adaptor domain that binds phosphotyrosine containing peptides; SH3: a polyproline peptide-binding adaptor domain; PTPase: phosphotyrosine phosphatase domain; Y-kinase: tyrosine kinase domain

same domain in a polypeptide. The TATA-binding protein (TBP) that ancestrally bound asymmetrically exists in all its extant forms with a homodimeric architecture of two tandemly repeated TBP DNA-binding domains (Figure 2).

3. *Hetero-multidomain proteins*: Proteins that are composed of domains that participate in either the same or successive steps in a pathway are frequently encountered in a variety of biological systems. The selective advantages of such architectures are clearly linked with the necessity for close functional interactions of the proteins in a pathway. Such fusions are particularly common in metabolic enzymes from eukaryotes, like the multifunctional aromatic amino acid biosynthesis protein (Aro1) that combines at least five distinct enzymatic domains into a single protein, including the shikimate kinase of the kinase family of P-loop ATPase and the dehydrogenase of the Rossmann fold (Figure 2).
4. "*Regulatory architectures" involving small molecule binding domains (SMBDs)*: A variety of low molecular weight compounds regulate responses to environmental stimuli, reaction rates in basic cellular metabolism, nutrient transport, and signal transduction cascades in biological systems. Some of the best-studied forms of small molecule–dependent regulation include allosteric control of enzyme activity, feedback regulation of biochemical pathways, and catabolite

repression. All these processes have selected for a variety of "regulatory architectures" that typically combine an SMBD with an effector domain (Figure 2). These latter domains are the actual agents of a certain biological activity, which is altered by the binding of a small molecule to the associated SMBD. Thus, we have SMBDs such as the ACT domain, which binds amino acids and other related small molecules, fused to a variety of catalytic domains in proteins such as homoserine dehydrogenase and aspartokinase. In these cases, the ACT domain binds substrates or downstream products and mediates the allosteric or feedback effect on the catalytic domains (Anantharaman *et al*., 2001).

5. "*Adaptor architectures" or fusions of adaptor domains with effector domains*: Very often, the performance of a certain biological function involves the targeting of a specific activity that resides in the effector domains to a certain cellular context. This context may be a subcellular location, or a precise protein complex or other biopolymers such as DNA or carbohydrates. The domains that recognize these contexts by binding specific target molecules pertaining to these contexts are generally termed adaptor domains. The most common of these architectures involve fusions of specific peptide-binding or protein-interacting domains with catalytic domains. These are abundantly represented by the fusions between adaptor domains such as the SH2, SH3, WW, and BRCT domains and catalytic domains such as protein kinase, GTPase activating protein, phospholipase, acetyltransferase, and ubiquitination-related domains (*see* Article 31, **Protein domains in eukaryotic signal transduction systems**, Volume 7). Yet other proteins are made up entirely of such adaptor domains, and act as "multiheaded" adaptors that bring together distinct protein complexes (Figure 2). Homophilic interactions are another common mode of action by which two proteins bearing the same adaptor domains, such as the DEATH superfamily of domains, associate with each other in a signaling pathway.

The above classes of domain architectures that are repeatedly reinvented in entirely unrelated proteins might be considered convergently favored solutions for problems in biological engineering in a domain-based world. Given that the above-discussed architectural classes are associated with specific teleological explanations, they represent a subtle source of contextual information that allows refinement of functional prediction of proteins when combined with more straightforward protocols of domain identification and nonglobular segment analysis (Figure 1).

6. Apprehending the "meta-picture": extraneous sources of contextual information in establishing protein function

Most biological systems can be conceptualized as graphs (networks) whose nodes represent individual proteins and whose edges represent the functional connectives that radiate out from a protein at a given node to its partners occupying adjacent nodes (*see* Article 30, **Contextual inference of protein function**, Volume 7). These connectives encompass a considerably diverse set of functional interactions:

1. *Physical interactions*: This includes a variety of direct interactions such as the tendency of two or more proteins to form a functional complex or enzyme–substrate interactions between two proteins.
2. *Indirect regulatory interactions*: This includes transcriptional control of the gene encoding a given protein by another protein, which is a transcription factor, or indirection regulation of a target protein through the synthesis or delivery of a small molecule messenger.
3. *Coexpression and colocalization*: Coexpression is specified by congruent expression patterns of two or more genes whose products are likely to participate in a similar biological process. Colocalization implies the similar subcellular targeting of two proteins, which in turn points to their potential functional interaction in a common organelle or cellular compartment. These functional connections are not mutually exclusive of the earlier-discussed connections.
4. *Genetic interactions*: These connections might arise because of any of the above types of interactions or the general participation of two gene products in a common pathway. Genetic interactions can be ultimately decomposed into a specific type of underlying biochemical interaction, but even in the absence of specific biochemical explanations, genetic interactions can provide useful contextual information for functional inference.

These functional interactions that anchor a protein to its place in a biological network can often help in providing contextual information that goes over and beyond the information provided by intrinsic features like the domain architectures. This extraneous contextual information is usually critical in translating the biochemical inferences gleaned from sequence analysis to the actual biological roles of proteins.

Prior to the postgenomic era, the establishment of these functional connections was the exclusive realm of focused biochemical and genetic experimentation. However, these days, a large amount of contextual information is directly available and can be used for different kinds of in silico analysis to determine biological functions of uncharacterized proteins through the principle of "guilt by association" (*see* Article 30, **Contextual inference of protein function**, Volume 7). The basic idea here is to establish a link between an uncharacterized protein and one or more functionally characterized proteins by means of one or more of the above functional connections. This can then be used to implicate a protein in a particular functional pathway or biological process (Figure 3).

The simplest forms of contextual information arise directly from genome sequence data and are usually in the form of phyletic profiles of orthologous proteins, conserved gene neighborhoods, and lineage-specific expansions of protein families. Yet other forms of contextual information have been obtained from a whole range of high-throughput experimental studies on model organisms such as *Escherichia coli, Saccharomyces cerevisiae*, *Caenorhabditis elegans,* and *Drosophila melanogaster.* These include construction of protein–protein interaction maps, development of single- and multigene knockout strains and microarray-based gene expression profiles under diverse physiological conditions and cell types. Additionally, the data from green fluorescent protein fusion studies have also

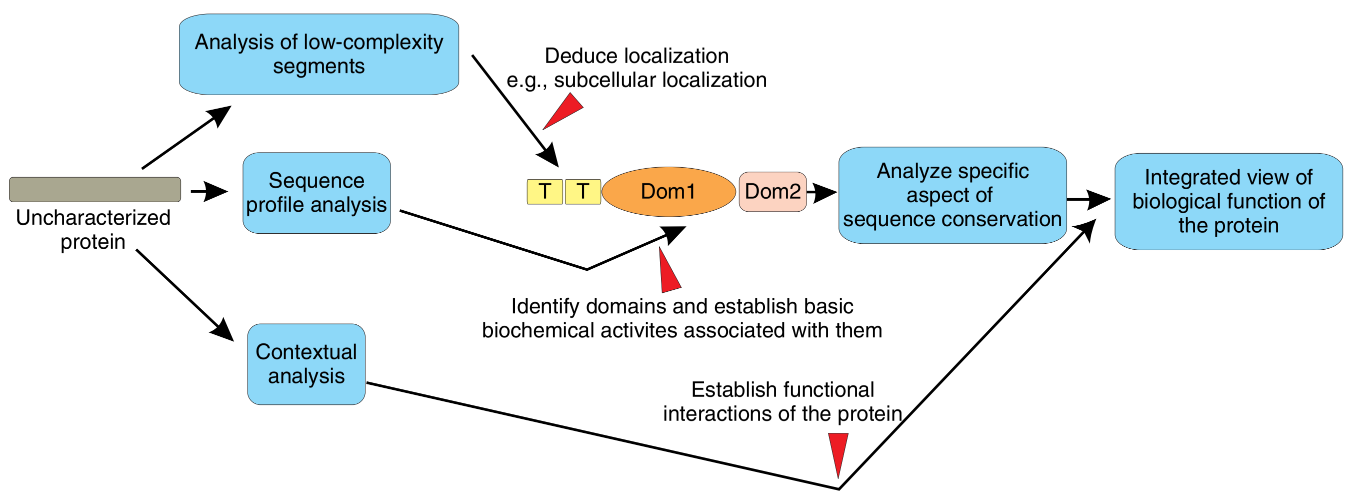

Figure 3 A general scheme for in silico functional inference for uncharacterized proteins. The grey box denotes the sequence of an uncharacterized protein prior to domain identification. The yellow boxes with T represent TM segments, while “Dom1” and “Dom2” represent two conserved globular domains that were detected in the protein

provided considerable information regarding subcellular localization of proteins in model organisms such as *S. cerevisiae* and *Schizosaccharomyces pombe*.

7. Overview of the section on protein sequence analysis and annotation

The confluence of various streams of data holds considerable promise in developing a unified basis for understanding biology in terms of the constituent modules of proteins and their functions (Figure 3). Accordingly, we have attempted to assemble a collection of articles in this section that provide primers regarding the various computational approaches that can be used to glean functional information from proteins. Some of the articles specifically explore the means of investigating nonglobular regions of proteins such as TM regions, signal peptides, and low complexity regions in making functional inferences and predicting protein localization (*see* Article 32, **Sequence complexity of proteins and its significance in annotation**, Volume 7, Article 33, **Protein repeats**, Volume 7, Article 37, **Signal peptides and protein localization prediction**, Volume 7, and Article 38, **Transmembrane topology prediction**, Volume 7). Other articles discuss the significance of conserved domains that are prevalent in specific cellular processes and systems such as signal transduction and chromatin organization (*see* Article 31, **Protein domains in eukaryotic signal transduction systems**, Volume 7 and Article 35, **Measuring evolutionary constraints as protein properties reflecting underlying mechanisms**, Volume 7). There is also a discussion of the application of modern sequence profile methods for the detection of distant relationships and domain discovery, and the role of curated protein classification databases in large-scale annotation of protein functions (*see* Article 36, **Large-scale, classification-driven, rule-based functional annotation of proteins**, Volume 7 and Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7). Finally, there is a perspective on the integration of various forms of contextual information to grasp function at the organismic level (*see* Article 30, **Contextual inference of protein function**, Volume 7).

Specialist Review

Contextual inference of protein function

Aswin Sai Narain Seshasayee

Anna University, Chennai, India

M. Madan Babu

MRC Laboratory of Molecular Biology, Cambridge, UK

1. Introduction

Ever since the first genome sequence of *Haemophilus influenzae* was determined in 1995, there has been an explosion in the number of organisms whose genomes have been completely sequenced and made available in public databases. As on December 2004, there were 235 organisms whose complete genome sequences are available, including that of human (Bernal *et al*., 2001). Such an exponential increase in the number of available sequences has led to the realization that to understand the biology of an organism, one has to be able to make sense of this sequence data. One way of reaching this end is by identifying the function of proteins and RNAs encoded in its genome.

Traditionally, computational methods used to assign protein function are based on the simple assumption that proteins with similar sequences (homologs) perform similar molecular function. In such homology-based methods, function of a protein is inferred by comparing its sequence against a database such as the nonredundant database or Swiss-Prot using powerful tools such as PSI-BLAST (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7) to pick up homologs and then making good use of any available information on the homologous protein (Aravind and Koonin, 1999b).

Even though homology-based methods, such as those described above, have been quite effective at predicting molecular functions of remote homologs, large gaps still exist in our knowledge. Several genes in any given organism remain uncharacterized, where even sophisticated homology-based methods fail to suggest any function (Madera *et al*., 2004). Moreover, higher-order function of a protein, such as the pathway in which it plays a role, cannot, in principle, be assigned using such methods (Huynen *et al*., 2000). It is here that homology-independent methods, which primarily utilize the context in which a gene exists, become useful in inferring function. Such methods, more generally termed contextual methods, make use of information about gene organization in multiple genomes, and data

obtained from large-scale functional genomics experiments such as gene expression, transcriptional interaction, and protein interaction studies.

In this article, we have classified homology-independent contextual methods to infer protein function into two major groups: methods that use genome sequence data and those that use information from large-scale functional genomics data.

2. Inferring function from genomic data

With a large number of genome sequences determined and many more in the pipeline, there is no paucity of data for gaining useful insights into protein function. In the following section, we discuss the different homology-independent contextual methods that use genome sequence data for inferring protein function.

2.1. Gene fusion

In a set of well-characterized proteins, it has been observed that pairs of interacting proteins or those that are functionally linked (e.g., involved in the same metabolic pathway) in one organism are fused into a single polypeptide chain in another organism. If two proteins are required to interact physically or are functionally linked, then it is likely that there is a selective pressure to produce them at the same time and at the same place within the cell, so that the chances that they interact are maximized. The best way to do it would be to have them as a part of the same gene product so that they are transcribed and translated at the same time and at the same place, thus allowing them to carry out their function efficiently. This logic has been exploited to predict pairs of interacting proteins by identifying instances of protein pairs that are fused in one organism but are found to be separate in another organism (see Figure 1a). A well-known example is the case where the genes encoding GyrA and GyrB in *Escherichia coli* are fused into a single-gene product, DNA topoisomerase, in yeast. Also illustrative is the case of gene fusions between evolutionarily mobile helicase and nuclease domains in DNA repair proteins, implying a general tendency of these domains to interact physically. An example is the fusion between PolIII subunit-like nuclease and DinG helicase in *Bacillus subtilis* (Aravind, 2000).

In one of the early computational analysis, Marcotte *et al*. (1999a) used genome sequence data and found that there are 6809 candidate interacting protein pairs in *E. coli.* The authors also used a three-step validation for their prediction: (1) ask whether the predicted pair of interacting proteins share a keyword between their annotations, which they show is very rare in randomly chosen pairs, (2) validate against experimental data, and (3) compare with results obtained from phyletic profiles (see Section 2.3 and Article 41, **Phylogenetic profiling**, Volume 7). Enright *et al*. (1999) showed that there are 215 proteins in the genomes of *Escherichia coli, Methanococcus jannaschii*, and *Haemophilus influenzae,* which are involved in 64 gene fusion events. In another similar study, it was shown that metabolic enzymes exhibited a profound 300% preference to exist as fused proteins over a control set of proteins (Tsoka and Ouzounis, 2000). This observation allowed them to conclude

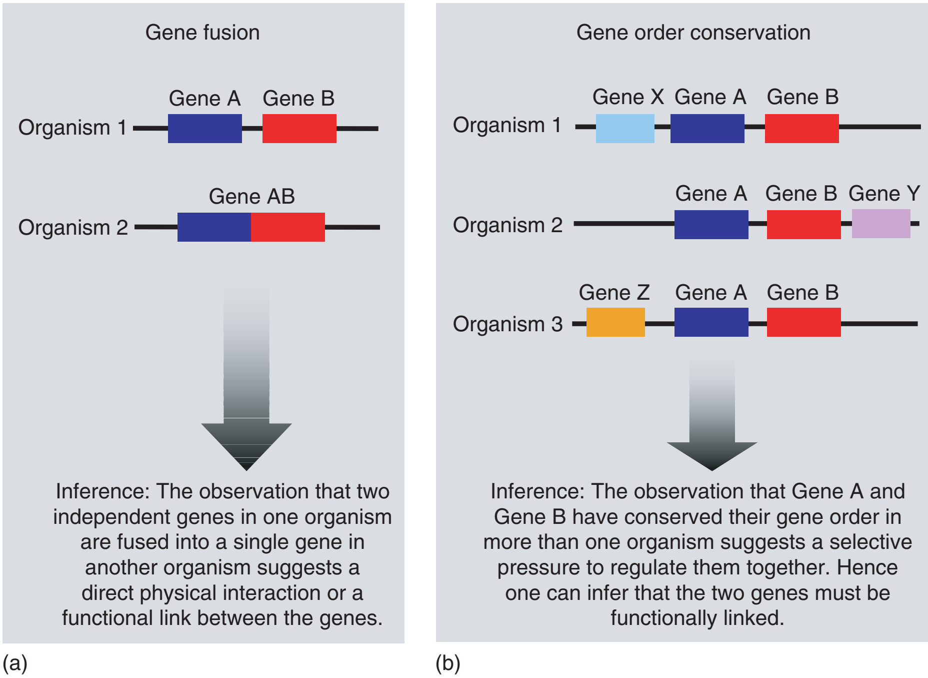

Figure 1 Figure illustrating inference of protein function from (a) gene fusion events and (b) conservation of gene order across multiple genomes

that proteins predicted to interact by detection of gene fusion events are more likely to be involved in metabolic pathways.

This method, while being useful, has a few pitfalls. In particular, this method could be confounded by evolutionarily mobile promiscuous domains that show fusions to other domains in a wide range of functional contexts. False-positives, with regard to prediction of physical interactions, may also crop up because it is perfectly possible that two fused protein domains do not interact physically but only functionally. The method cannot differentiate between interacting and noninteracting homologs. Another important problem associated with this method and the other genome sequence–based methods, which will be described later, is the difficulty in identifying true orthologs. If the stand-alone polypeptides and the individual components of the composite protein under consideration are really paralogs and not orthologs, we will end up with a false prediction (Marcotte *et al*., 1999a; Galperin and Koonin, 2000).

2.2. *Gene order conservation and co-occurrence of genes in operons*

Comparative genomic analyses among closely related species revealed an important fact that it is very rare for organisms to conserve gene order. Given the extremely high rate of recombination in bacterial genomes, the probability that the order of

genes is maintained across many organisms is negligible. However, when gene order conservation is indeed observed, it only means that it is due to a selective pressure that the genes are kept together. This gene order conservation might mean that the two genes concerned encode products that either interact functionally or physically (see Figure 1b). In fact, Demerec and Hartman (1959) observed that the "mere existence of such arrangements shows that they must be beneficial, conferring an evolutionary advantage on individuals and populations which exhibit them" (Overbeek *et al*., 1999a). When interacting proteins are coded for by a polycistronic mRNA, the collection of adjacent genes is called an *operon*. Operons are common in prokaryotes and proteins involved in a particular biochemical pathway are generally clustered together to form an operon.

While this method is conceptually simple, in silico identification of operons in genome sequence is not trivial (*see* Article 20, **Operon finding in bacteria**, Volume 7). It was observed that the number of instances of functionally linked gene pairs increased with the increase in the number of organisms considered for the analysis. Overbeek *et al*. (1999a) have shown that the number of pairs of close bidirectional best hits (PCBBHs) identified in local alignment sequence searches is related to the square of the number of genomes considered. Data from 24 organisms pointed to the presence of 34 644 PCBBHs. More recent information on function inference from operons has shown that there are 58 498 PCBBHs in 31 genomes (Overbeek *et al*., 1999b). With the number of genome sequences being made available increasing exponentially, the predictive power of this method should increase at a much higher rate.

2.3. *Correlated and anticorrelated occurrence of genes across many genomes*

The idea behind this method described by Pellegrini *et al*. (1999) is that functionally related genes evolve in a correlated fashion across genomes. This implies that these genes should coexist across a set of organisms displaying the function of interest. In this technique, each gene is represented by a "phyletic profile" (*see* Article 41, **Phylogenetic profiling**, Volume 7), which is a string of n characters, where n is the number of organisms considered. Each of these characters may be either + or − representing the presence or absence of the gene of interest in the corresponding organism. The genes are then clustered into groups on the basis of their phyletic profiles. Gene products that belong to a cluster are then predicted to be functionally linked (see Figure 2).

In their study, Pellegrini *et al*. (1999) characterized 4217 genes from *E. coli* using this method. The number of organisms used to create the phyletic profile was 16. As an example, proteins with functions associated with the ribosome are discussed (Pellegrini *et al*., 1999). The ribosomal protein RL7 has homologs in 10 of the 11 eubacterial genomes and in yeast, but not in archaea. More than 50% of *E. coli* genes with function associated with the ribosome share the phyletic profile with RL7. Several uncharacterized proteins were found to fall under this cluster, and the authors state that it is likely that these uncharacterized proteins have functions associated with the ribosome. These proteins whose function has been

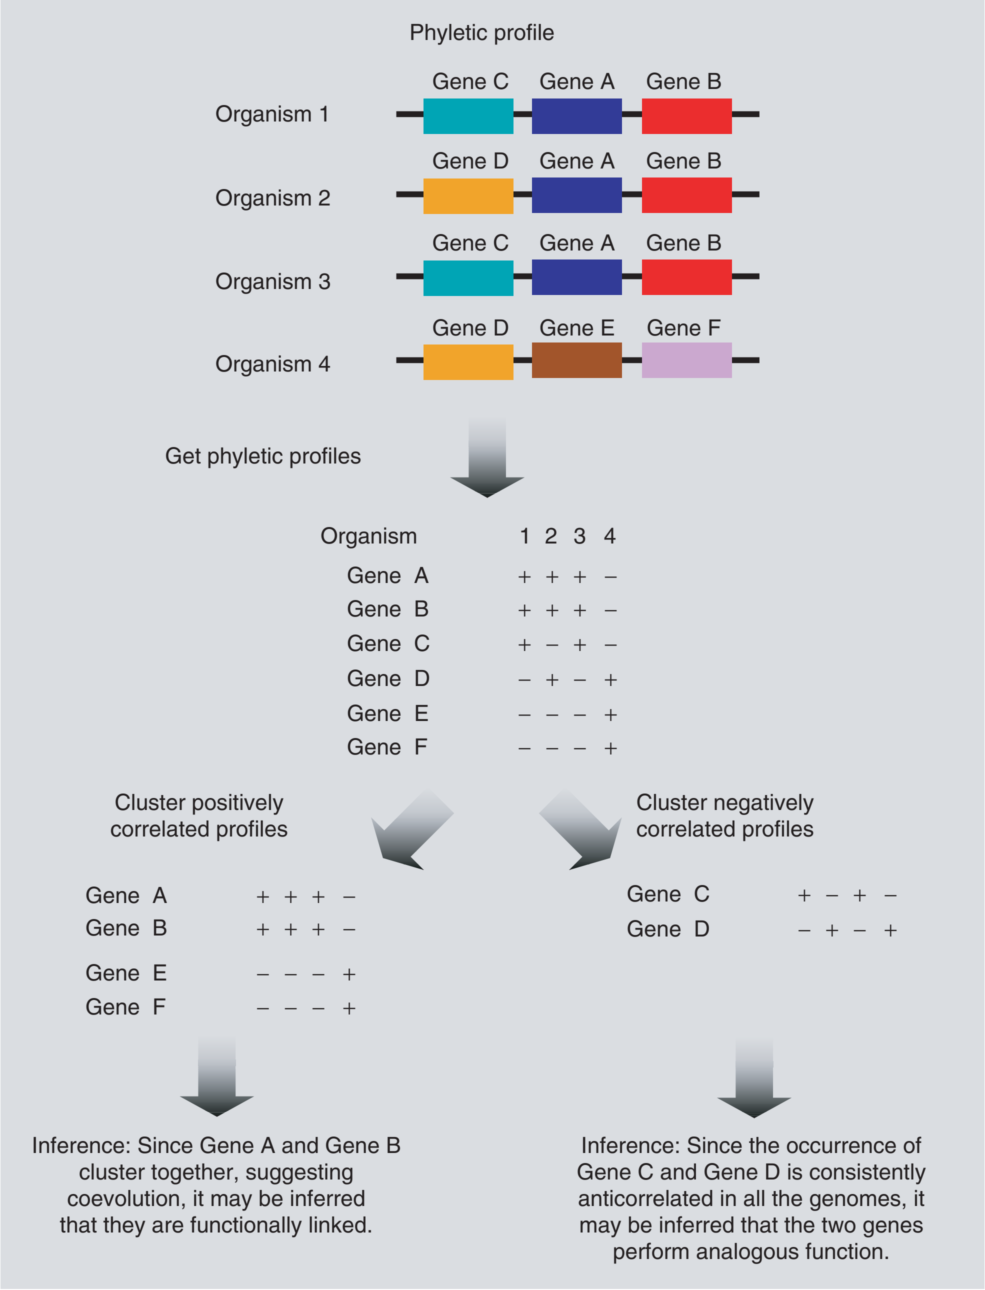

Figure 2 Inference of protein function using correlated or anticorrelated phyletic profiles of clusters of genes. "+" represents presence of the gene and "–" represents absence of the gene

inferred by this method share no sequence similarity to the characterized protein such as RL7, and hence their role in the functioning of the ribosome could not have been inferred by homology-based methods. Another example of application of this method to inferring function is the subcellular localization of proteins. It is based on the idea that proteins that localize to a particular cellular compartment have a similar phyletic profile. This method, when applied to *Saccharomyces cerevisiae* identified 361 nucleus-encoded mitochondrial proteins with 50% accuracy and 58% coverage (Marcotte *et al*., 2000).

Just like how similarity in phyletic profiles of genes can be used to infer the function of a protein, anticorrelation of phyletic profiles can also be used to identify instances of nonorthologous gene displacement, that is, instances in which nonhomologous proteins perform the same function in different organisms. The principle behind this method relies on identifying cases in which two genes have dissimilar phyletic profiles, that is, if the first gene is present in an organism, then the second gene is absent in the same organism. If this observation is consistent for a large number of organisms considered, then one can infer that the two proteins perform analogous function and evolution has selected for one of the two proteins, discarding the other (see Figure 2).

An example of how anticorrelated phylogenetic profiles have enabled us to understand a well-characterized metabolic pathway such as glycolysis involves the enzyme fructose-1,6-bisphosphate aldolase (FBA). This enzyme catalyzes the step where fructose-1,6-bisphosphate is cleaved to glycerol-3-phosphate and dihydroxy-acetone phosphate. While this enzyme is present in most bacteria and eukaryotes, it is absent in Chlamydiae and Archaea. However, a second enzyme DhnA in these organisms forms an almost-perfect complementary phyletic pattern against a set of reference genomes, indicating that this enzyme is the only FBA in Chlamydiae and Archaea (Galperin and Koonin, 2000). In another case, seven enzymes belonging to the 15-step thiamin biosynthesis pathway were found to have been displaced by analogous proteins. These predictions have been verified experimentally. Importantly, this led to the assignment of function for three proteins, till then uncharacterized. An example is the displacement of thiamin phosphate synthase, first described in *E. coli,* by genes orthologous to the hypothetical ORF MTH861 in *M. thermoautotropicum* (Morett *et al*., 2003).

2.4. *Conservation of bidirectionally transcribed gene pairs*

Yet another contextual method for inferring function from genomic data is the identification of conservation of gene orientation of adjacent, bidirectionally transcribed gene pairs across genomes (Korbel *et al*., 2004). These bidirectionally transcribed gene pairs may be regulated by a pair of overlapping promoter elements. Such gene organization is beneficial as it offers a method of transcriptional regulation distinct from operons (Korbel *et al*., 2004; Warren and ten Wolde, 2004). It is also worthwhile to note that while organization of convergently transcribed gene pairs is rapidly lost during evolution that of divergently transcribed gene pairs is not. Systematic analysis carried out by Korbel *et al*. (2004) shows that over 5000 divergently transcribed gene pairs are conserved across distantly related

organisms and that 26% of all *E. coli* genes are divergently transcribed pairs, a quarter of which are conserved in a distant evolutionary clade. There are 6.5 times more divergently transcribed gene pairs than convergently transcribed ones. Such conservation of bidirectionally transcribed gene pairs may be due to the pressure of coexpression, similar to the pressure that maintains the operon structure. About 87% of gene pairs conserved across distant genomes have correlated gene expression, with a Pearson correlation coefficient value greater than 0.6 (see Figure 3).

Bidirectionally transcribed gene pairs may more than just be coexpressed. Over 71% of such pairs identified in *E. coli* were classified as "RX" by the authors, where one gene product is a transcriptional regulator (R) and the other belongs to some other class of protein (X). Interestingly, most of such RX pairs have been shown to be autoregulatory. Thus, if a protein has been classified as a transcription factor by homology-based methods (Aravind and Koonin, 1999a; Perez-Rueda and Collado-Vides, 2000; Madan Babu and Teichmann, 2003), then its transcriptional target in vivo can be determined using this method. For example, using this method, it was shown that prokaryotic members belonging to the orthologous group KOG2969 (*see* Article 90, **COGs: an evolutionary classification of genes and proteins from sequenced genomes**, Volume 6) are involved in regulating the expression of ribosome-associated genes in alpha-proteobacteria. It has been experimentally shown that KOG2926, whose gene is divergently transcribed from the nearby mitochondrial ribosomal protein S2 (RpsU) gene, is indeed the transcriptional regulator

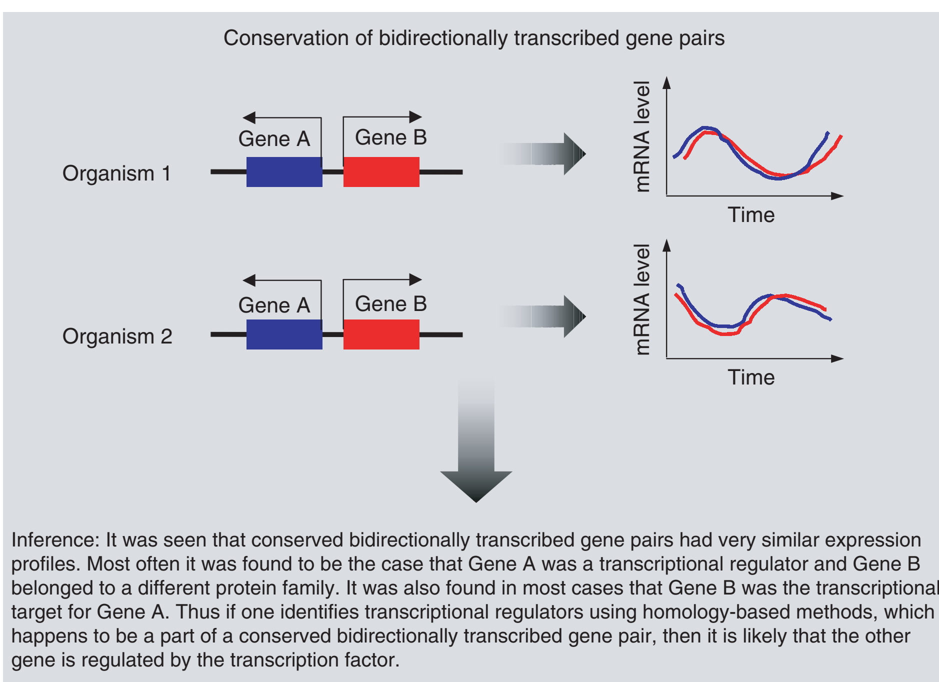

Figure 3 Determining the function of proteins from conservation of bidirectionally transcribed gene pairs

of rpsU. The efficiency of this method, like that of any other genomic context method, is dependent on the number of genomes sampled (Korbel *et al*., 2004).

3. Inferring function from large-scale experimental data

Coupled with the explosion in the availability of complete genome sequence for several organisms is public access to large-scale experimental data on interactions between the cellular components and to data on gene expression for several organisms obtained using microarrays. These interactions may be protein–protein, protein – metabolite, or protein–nucleic acid.

The following section will focus on methods that utilize data on the interactions between the cellular components and gene-expression studies to infer functions of uncharacterized genes. The set of all interactions mediated by cellular components can be conceptualized as a graph or a network, in which each cellular component is represented as node and interaction between the two components as edges or arcs. Such cellular networks can be used to infer protein function in the context of a biological process (Barabasi and Oltvai, 2004; Xia *et al*., 2004). For instance, a link between a functionally uncharacterized protein X and well-characterized protein(s) will enable one to place the function of X in context of the function of the characterized protein(s) to which it is linked (see Figure 4).

In the following section, we review four different methods of inferring protein function using data obtained from the different large-scale experiments.

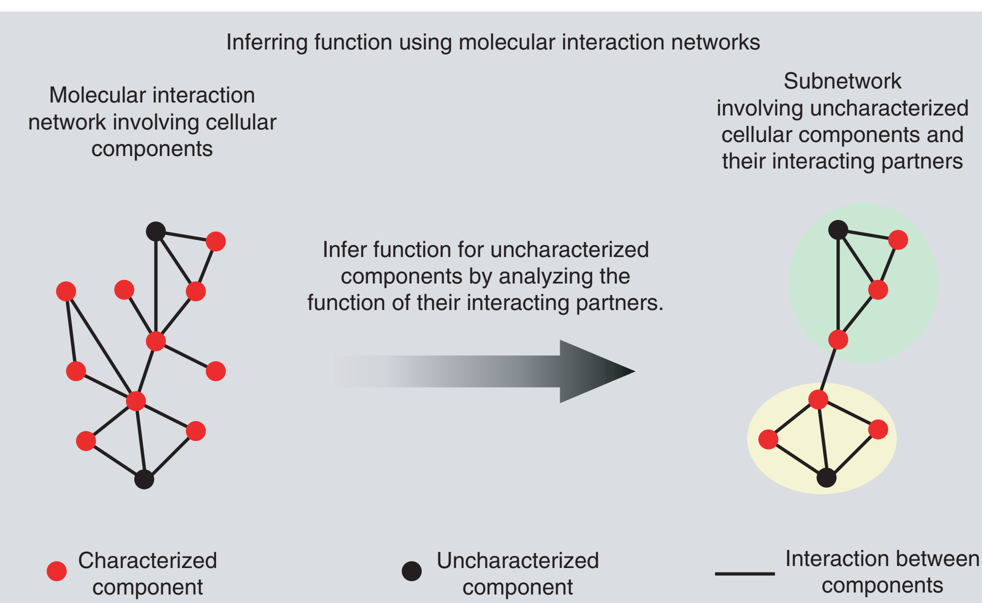

Figure 4 Figure illustrating the general idea of inferring function of an uncharacterised cellular component based on its links with other characterized components in a molecular interaction network

3.1. Protein–protein interaction network

Identification of cellular protein–protein interaction networks has become possible due to the development of high-throughput techniques such as the yeast two-hybrid experiment and the tap-tag method (*see* Article 37, **Inferring gene function and biochemical networks from protein interactions**, Volume 5). Protein–protein interaction networks derived using the two-hybrid method are available for *D. melanogaster* (Giot *et al*., 2003), *C. elegans* (Walhout *et al*., 2000), *S. cerevisiae* (Uetz *et al*., 2000), *H. pylori* (Rain *et al*., 2001), and the T7 bacteriophage (Bartel *et al*., 1996). Such experimentally derived networks can be analyzed using computational approaches and useful functional information can be obtained from them.

When a protein–protein interaction network is rendered in such a way that specific functional categories are highlighted, it will be observed that proteins belonging to the same functional category cluster together. It has been shown that 72% of interactions between experimentally characterized proteins in such networks are between pairs belonging to the same functional class. The significance of this number is illuminated when we see that this percentage is only 12% when the network is randomly divided into different categories. Linkages between proteins belonging to different functional categories are also possible. The difficulty with interpreting such linkages is that they may be false-positives or genuine cross talk between related pathways. It was also determined that 78% of interactions between proteins with known cellular localization involved proteins sharing at least one cellular compartment (Schwikowski *et al*., 2000; Tucker *et al*., 2001).

Protein–protein interaction networks have been used to assign functions to a number of previously uncharacterized proteins. A common approach for assigning function using protein–protein interaction network is what is known as the majority-rule assignment. This technique assigns function on the basis of most common functions present among the characterized interacting partners (see Figure 5). Vazquez *et al*. (2003) have used interactions between uncharacterized proteins in an iterative majority-rule technique to yeast and identified 2238 interactions among 1826 proteins (Vazquez *et al*., 2003).

Map of 957 interactions involving 1004 yeast proteins generated by Uetz *et al*. (2000) has yielded novel insights into functions of several proteins. For instance, two yeast proteins of unknown function, which were seen to interact with each other, also bind to ornithine aminotransferase. This implies that they may be involved in arginine metabolism. Novel interactions between proteins involved in the same biological function were also shown. Their data also shows that novel interactions exist between proteins involved in diverse biological processes. For example, three snRNPs were found linked to the ribosomal protein S28. This might indicate a role for S28 in RNA splicing or, alternatively, a novel role of snRNPs in translation or ribosome biosynthesis (Uetz *et al*., 2000).

This method, like any other, is not free from operational difficulties and errors. The yeast two-hybrid method can only detect binary interactions, but in reality many proteins function as protein complexes. This may partly be overcome by the tap-tag method, which is used to purify protein complexes and characterize them. Even in such cases, interactions between the individual subunits of the complexes are not known. Yeast two-hybrid also gives rise to many false-positive interactions

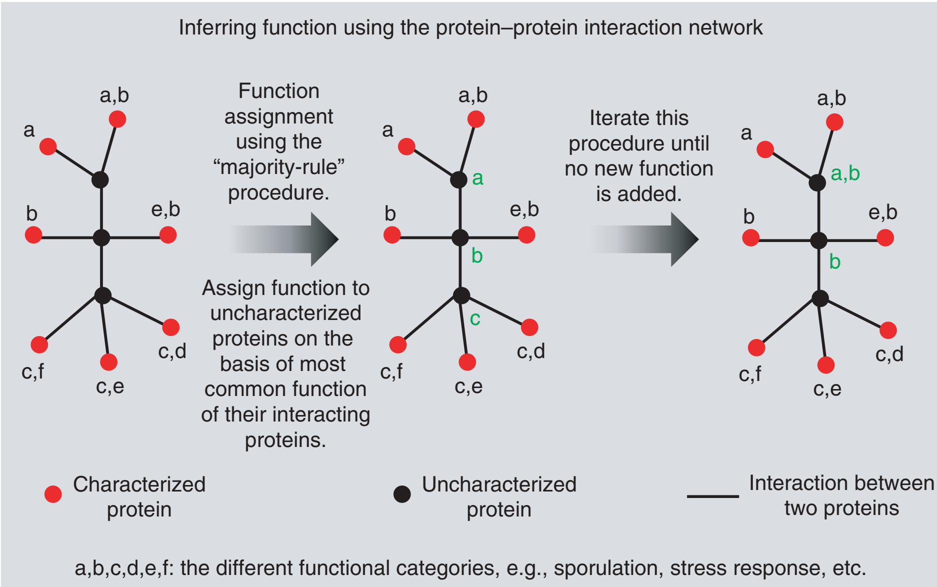

Figure 5 Figure demonstrating the use of majority-rule assignment (see text) of function from protein–protein interaction networks. In this figure, labels a–f in black represent arbitrary functional class assigned to well-characterized proteins (nodes) in the network. Labels a–c in green are the functions of uncharacterized proteins (nodes) inferred using the majority-rule method

because of the nature of the experiment – since the interaction is tested in the nucleus, the local cellular environment may be different and it is possible that the interaction is mediated by a third protein, in which case the two proteins shown to interact by the two-hybrid system do not really interact directly (Aloy and Russell, 2002; von Mering *et al*., 2002).

3.2. *Transcriptional regulatory network*

Transcriptional regulatory networks are deciphered by carrying out ChIP-chip experiments, which specifically identify DNA sequences that can interact with transcription factors. Data generated are called location data, and are again useful in assigning function to proteins (see Figure 6).

A transcriptional regulatory network has been generated by Lee *et al*. (2002) for yeast. This study used 141 transcription factors (TFs) that were listed at that time in the Yeast Proteome Database. Out of these 141 TFs, only 106 gave useful information, as experimental modification caused loss of function in 17 proteins and the others could simply not be detected. This network showed that 2343 of 6270 yeast genes were bound by one or more of the 106 TFs when the cells were grown in rich media. More than one-third of these promoters were bound by more than one TF. In the assembled network, six network motifs were identified. Network motifs are short patterns of interconnections that recur at many places in the network at frequencies much higher than seen in random networks of a similar

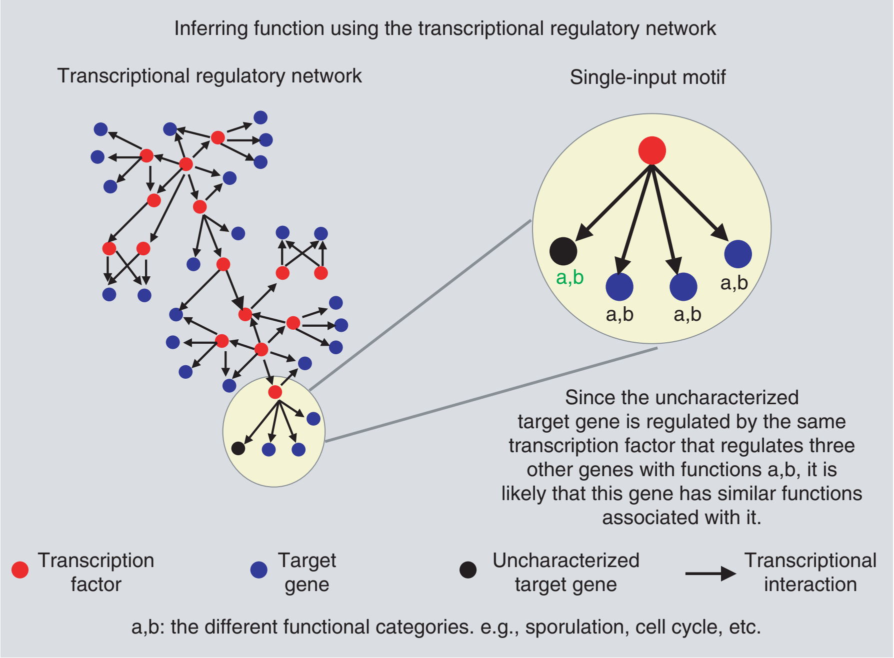

Figure 6 Determination of protein function using the context in which it occurs in the transcriptional regulatory network

size (Lee *et al*., 2002; Shen-Orr *et al*., 2002). In the yeast network, the motifs identified were the following: autoregulation, multicomponent loops, single input, multi-input, feed-forward loops, and regulator chain. Since each network motif has a specific information-processing task (Shen-Orr *et al*., 2002), such regulatory motifs could be used to make functional assignments. For example, Fhl1, a protein with function unknown was found to be involved in a single-input motif-regulating multiple genes involved in ribosome biosynthesis. This protein was also involved in a multi-input motif. Experiments have showed that a mutation in this protein caused serious defects in the ribosome synthesis machinery (Lee *et al*., 2002).

Knowledge about the function of proteins could be extended using such networks. For example, the protein Phd1 that is involved in pseudohyphal growth in nutrient stress conditions was shown to interact with proteins involved in general stress response and in regulation of metabolism (Lee *et al*., 2002).

More recent transcriptional regulatory network generated for yeast by Harbison *et al*. (2004) has revealed 11 000 interactions mediated by 203 TFs. In this study, predictions of TF-promoter pairs were validated using comparisons across four species of yeast. This work discovered and rediscovered promoter elements. Functional correlations, to confirm previous functional assignments, could be made to the network connections. For example, six cell-cycle transcriptional regulators were found to bind to the promoter for YHP1, which is involved in the regulation of the G1 phase of the cell cycle.

3.3. *Gene coexpression network*

Since proteins involved in the same pathway or those that are part of the same protein complex are coregulated at the transcriptional level, gene-expression data can be used to make functional inferences. However, coexpression alone will not necessarily mean functional relationship (Mateos *et al*., 2002). On the other hand, when a pair of gene is consistently coexpressed across large evolutionary distances, this method becomes a powerful tool to infer protein function (Teichmann and Madan Babu, 2002; Stuart *et al*., 2003; van Noort *et al*., 2003; McCarroll *et al*., 2004) (see Figure 7).

Stuart *et al*. (2003) have constructed a gene coexpression network (*see* Article 60, **Extracting networks from expression data**, Volume 7) for a set of metagenes. Metagenes are defined as sets of genes that are evolutionarily conserved across diverse organisms (effectively the term metagene is identical to a group of orthologous genes). In such a network, metagenes are represented as nodes and gene coexpression between a pair of genes as links. In their work, they first characterized 6307 metagenes using the following organisms: human, fly, worm, and yeast. For each pair of metagenes, coexpression was studied and gene pairs whose expression was significantly correlated across multiple organisms were identified. Expression was studied only for metagenes because the evolutionary conservation of these genes implies that the network covers only core biological processes. This

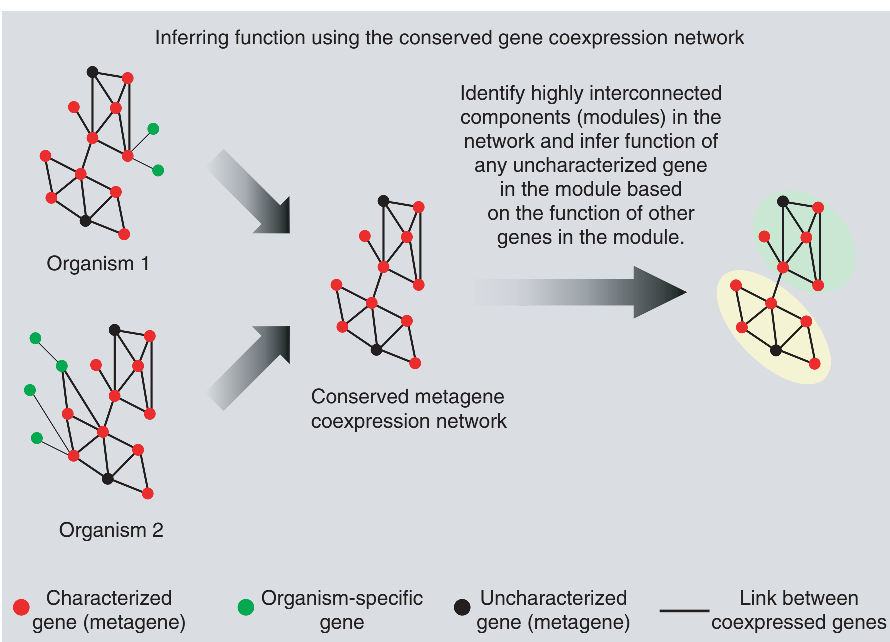

Figure 7 Use of conserved gene coexpression networks to determine protein function. The method initially identifies metagenes, which are groups of orthologous proteins across the different species. For each organism, a gene coexpression network is determined and the part of the network that is conserved in the set of organisms considered is referred to as the conserved metagene coexpression network

coexpression network comprised 3416 metagenes connected by 22 163 interactions. As a next step, the authors used a visualization technique in which metagenes were placed next to each other at a distance in proportion to their level of coexpression. Highly connected and conserved regions in the network could be visualized as peaks in the map. Such visualization led to the identification of 12 "components" – regions containing a large number of interconnected metagenes. These components were the following: signaling, ribosome biogenesis, energy generation, proteasome, cell cycle, general transcription, animal specific, translation, ribosomal subunits, secretion, neuronal, and lipid metabolism (Stuart *et al*., 2003).

The function of three uncharacterized genes was determined using this method. It was found that these proteins were coexpressed with genes involved in cell proliferation and cell cycle. Two other proteins known to function in other cellular processes also coexpressed with the above set of metagenes. Experimental verification of these results showed that all these five proteins were overexpressed in human pancreatic cancers relative to normal tissue and hence are involved in cell proliferation. Thus, by analyzing such coexpression networks, one can identify previously unknown proteins involved in well-characterized biological processes.

3.4. Integration of different data types

The methods discussed in the previous sections make use of a single type of data to infer protein function. The next logical step is to integrate different types of data to achieve this objective.

Marcotte *et al*. (1999b) have integrated data from phyletic profiles, gene fusion, and gene expression with the experimentally determined protein–protein interaction networks in yeast and identified 4130 links of very high confidence. They use this network to assign function to proteins. The yeast ORF, YGR021 W, was assigned a function related to mitochondrial protein synthesis. The function of Sup35 was extended to beyond its role as a translation release factor and in guiding nascent proteins to their cellular locations. Sup35 shows both correlated evolution and expression pattern with a yeast chaperonin system thought to aid in the folding of newly synthesized actin and microtubules.

Bar-Joseph *et al*. (2003) have combined gene-expression data and location analysis data to assign functions to proteins. They have done this because they realized that location analysis, while identifying what interacts with what, does not throw light on the type of interaction, that is, whether the interaction activates or represses transcription. To infer this, it is best to use gene-expression data. The algorithm that they have developed, namely, GRAM (Genetic Regulatory Modules), clusters sets of genes to which a common TF is bound. From this set, a subset of genes with correlated expression is derived. Positive correlation between TF binding and expression level indicates that the regulator protein is an activator. The integration of the two types of data allows a relaxation of the conditions set to identify a binding event. This will bring down the number of false-negatives while not substantially increasing the rate of false-positives. This reduction in stringency allowed six new genes to be identified as targets of Hap4, a well-characterized protein involved in regulation of oxidative phosphorylation and respiration.

In another recent work, Luscombe *et al*. (2004) developed an approach called SANDY (Statistical Analysis of Network Dynamics), which integrates gene-expression data with the transcriptional regulatory network to identify condition-specific transcriptional regulatory networks. By integrating these two sources of information, novel insights about the dynamic nature of transcriptional regulatory networks were obtained. For instance, this approach led them to identify “master regulators” that are important in particular cellular processes, such as sporulation and cell cycle. This approach additionally helped in identifying condition-specific transcription factors and their transcriptional targets for a given cellular condition such as stress and DNA damage.

4. Conclusions

The above, recently developed methods for protein function prediction have created a paradigm shift in our perspective toward understanding proteins. The classical view of protein function in terms of its molecular properties such as catalysis or ligand binding is being complemented by what is known as contextual or cellular function (*see* Article 29, ***In silico*** **approaches to functional analysis of proteins**, Volume 7). It is defined as the understanding of protein function in terms of the pathways or intracellular subnetworks in which the protein might be expected to play a role (Fraser and Marcotte, 2004; Palsson, 2004). The actual role it plays in this context would need to be elucidated by further experimentation. As in the case of homology-based methods, it is again due to the availability of a large volume of organized data that nonhomology-based methods to infer protein function have become feasible. Such large-scale methods for predicting protein function becomes more important in light of the situation where over a thousand genes in the most characterized bacterial genome, *E. coli*, remain known only as hypothetical ORFs.

Protein domains in eukaryotic signal transduction systems

Kay Hofmann
Memorec Biotec GmbH, Köln, Germany

1. Functional domains

Originally, the concept of protein domains was derived from the analysis of three-dimensional structures (*see* Article 68, **Protein domains**, Volume 7). While small proteins typically have a "monolithic" structure consisting of a single fold, larger proteins can follow two different architectural principles. Some of them just form larger monolithic structures, while the majority of large proteins consist of several smaller folding units, the so-called domains. Structural domains can fold independently from the rest of the proteins, and each one has its own hydrophobic core region (*see* Article 69, **Complexity in biological structures and systems**, Volume 7). As a consequence of their autonomous folding capabilities, domains can often be excised from their host protein and pasted into a different protein context, without major changes in fold or function. Evolutionary processes such as exon shuffling and gene duplication, -fusion or -fission have created the multidomain "mosaic" structure found in many protein classes, a prime example being proteins involved in eukaryotic signal transduction pathways (Bork *et al*., 1997; Ponting *et al*., 1999; *see also* Article 9, **Modeling protein evolution**, Volume 1).

In the course of domain evolution, the structural fold and key functional aspects have been kept largely intact. Some domain types have proven to be very successful as mediators of a particular unit function, and variants are found over and over again in extant proteins. By a combination of bioinformatical and experimental approaches, it has been possible to detect protein domains even in the absence of a three-dimensional structure (Copley *et al*., 2002). Here, functional protein domains appear as "homology domains", that is, as regions of local sequence similarity in proteins that are otherwise unrelated. The exhaustive detection of homology domains in signal transduction proteins has been – and continues to be – an important prerequisite for understanding the physiological importance of these proteins (Attwood, 2000; Hofmann, 1998; Hofmann, 2000).

As many homology domains require sophisticated sequence analysis method for their detection, a number of tools, databases, and WWW servers have been set up to help the nonspecialist with that important task. Information on homology domains can be stored in the form of so-called Hidden Markov Models (HMMs)

or generalized profiles (GPs) (Hofmann, 2000; *see also* Article 91, **Classification of proteins by sequence signatures**, Volume 6). Relevant databases, which maintain information on all domain types found in signal transduction proteins, are discussed in more detail elsewhere in this book (*see* Article 83, **InterPro**, Volume 6, Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6, and Article 86, **Pfam: the protein families database**, Volume 6), an overview of the most important resources is given in Table 1. InterPro is a meta-database combining information stored in several domain databases (Mulder *et al*., 2003). Thus, the signaling domains described in the remainder of the text will be referenced by their InterPro accession numbers, listed in Tables 1 to 5.

2. Eukaryotic signaling systems

Eukaryotic cells must respond to a large number of external stimuli, which are typically sensed by means of specific receptors localized on the cell surface. As a result of such stimulation, cells have a large repertoire of possible responses, including increased or decreased proliferation, differentiation, or apoptosis. On the molecular level, these responses can be mediated by increased or decreased expression of specific genes, and also by changes in the translation level of

	IPR001578	UCH type (for ubiquitin)
	IPR003653	ULP type (for sumo etc.)
	IPR003323	OTU type (for ubiquitin?)
	IPR006155	Josephin type (for ubiquitin?)
Recognition	IPR000449	UBA (for ubiquitin, NEDD8)
	IPR003903	UIM (for ubiquitin)
	IPR003892[a]	CUE (for ubiquitin)

[a]Domain family also includes members with different activities.

particular mRNAs or in the stability of specific protein products. Eukaryotic cells have developed a number of pathways for conveying signals from the cell surface to the transcription-, translation-, or degradation machinery (Pawson, 2004). In some instances, there is a simple and straightforward pathway leading from a cell surface receptor to a transcriptional regulator. More frequently, however, signal transduction pathways look – at first sight – unnecessarily complicated and involve a multitude of intermediary components. The reason for this complexity lies most

Table 5 Functional domains in signaling adaptors

Role	InterPro	Subtype
Proline-based motif recognition	IPR001452	SH3
	IPR001202	WW
Death domain like 6-helix bundle	IPR000488	Death domain (DD)
	IPR001875	Death effector domain (DED)
	IPR001315	Caspase recruitment domain (CARD)
	IPR004020	Pyrin domain (PYD)

probably in the requirement for cells to integrate the signals coming from different sources before mounting the most appropriate response. The components of signal transduction pathways have evolved to allow for a well-balanced amount of cross talk between pathways. In many instances, the whole concept of an isolated "signal transduction pathway" is not really tenable, and it appears more appropriate to talk of a "signal transduction network" instead.

2.1. Modularity in signal transduction

A hallmark of eukaryotic signal transduction proteins, starting from the cell surface receptor down to the final effector component, is their modular architecture (Bork *et al*., 1997). As a common mode of action, the receptors transform the external signal (e.g., the binding of a ligand) into a different, intracellular signal, which is then recognized by a downstream component and potentially converted into a third signal and so forth. Canonical signal transduction proteins comprise several receptor- and effector-functionalities, sometimes augmented by additional regulatory components, all of which are encoded by different domains. Besides the generation and the detection of a signal, the termination of the signal can be of crucial importance. Thus, most signal transduction systems also include dedicated components for signal termination, which are also encoded by specific domain types. It would be outside the scope of this chapter to mention, or even to discuss all signal transduction pathways employed by eukaryotic cells. Figure 1 shows three well-studied signaling paradigms that will be used as examples for the following paragraphs.

Growth factor signaling, shown in Figure 1(a), was the first signaling pathway to be understood in detail and is still among the most complex pathways known (Pawson, 2004; *see also* Article 117, **EGFR network**, Volume 6). This pathway makes use of three widely used signaling paradigms: proximity activation of enzymes, protein phosphorylation, and GTPase signaling. In brief, the cell surface receptor binds the growth factor by its extracellular domain, leading to a receptor dimerization that activates the tyrosine kinase domains found in the cytoplasmic portion of the receptor. The resulting tyrosine phosphorylation of the receptor is sensed by the SH2-domains of a downstream component, which transduces the signal via a GDP/GTP exchange protein to the small GTPase Ras. The GTP-bound Ras in turn transduces the signal to a downstream cascade of kinases, eventually resulting in MAP-kinase activation. Finally, MAP-kinase phosphorylates a large number of target proteins, including transcriptional regulators. Each of the generated downstream signals has a specialized system for signal termination.

Cytokine signaling, shown in Figure 1(b), employs a simpler pathway from receptor dimerization to transcriptional regulation (Shuai and Liu, 2003). Here, the receptor does not contain a kinase domain but rather binds noncovalently to Jak-kinases and activates them upon receptor dimerization. The resulting autophosphorylation of Jak-kinases recruits factors of the STAT family via an SH2 domain. Subsequently, the STAT proteins themselves become phosphorylated, which allows them to translocate into the nucleus where they work as transcription

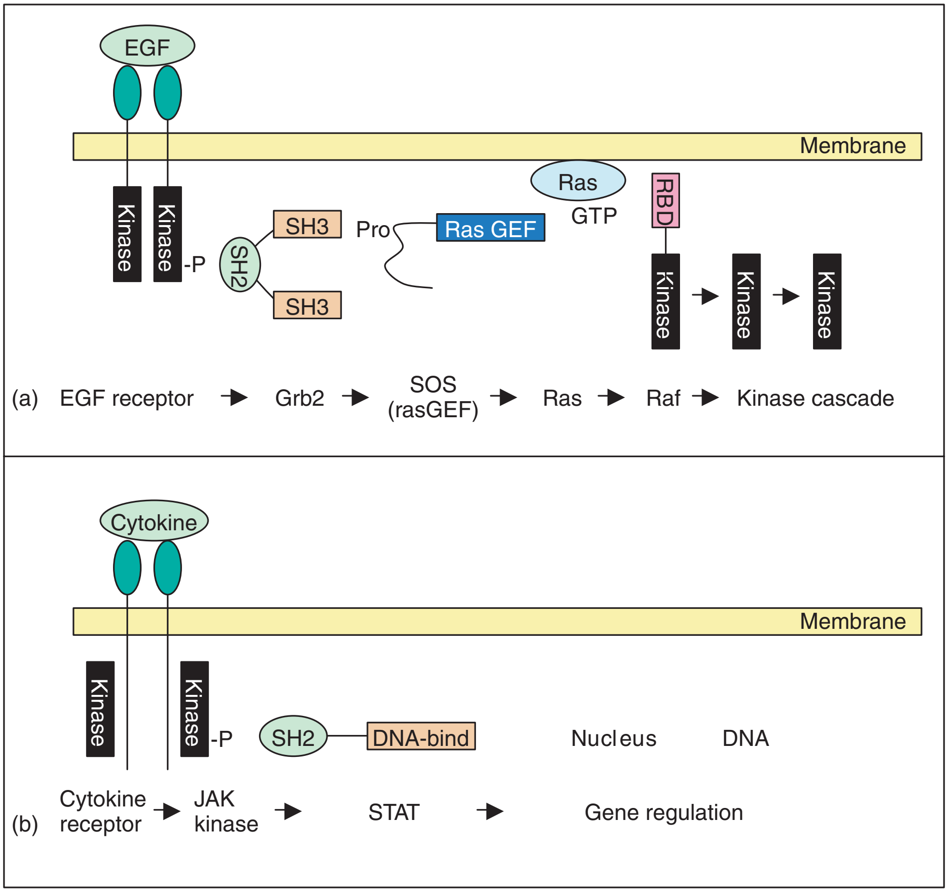

Figure 1 Simplified representation of three example pathways discussed in Section 2.1. (a) Growth factor signaling. The growth factor EGF and the membrane-associated Ras proteins are indicated by colored bubbles. The other signal transduction proteins are represented by their differently colored domains. The names of the corresponding proteins are given at the bottom of the figure. Interacting domains are shown juxtaposed to each other. Full domain names are given whenever possible. Abbreviated domain names are "RasGEF" for Ras GDP/GTP exchange domain, and "RBD" for the Ras-binding domain in the Raf kinase. (b) Cytokine signaling. Representation analogous to Figure 1(a). (c) Death receptor signaling. The trimeric death-ligand (e.g., FasL) and the mitochondrial proteins Bid and Cytochrome C are indicated by colored bubbles. The signal transduction proteins are represented by their differently colored domains, where DD, DED, and CARD mean "death domain", "death effector domain", and "caspase recruitment domain" respectively. Interacting domains are shown juxtaposed to each other. Caspase-8 cleaves Bid and Caspase-9 cleaves proCaspase-3, all other interactions are binding events

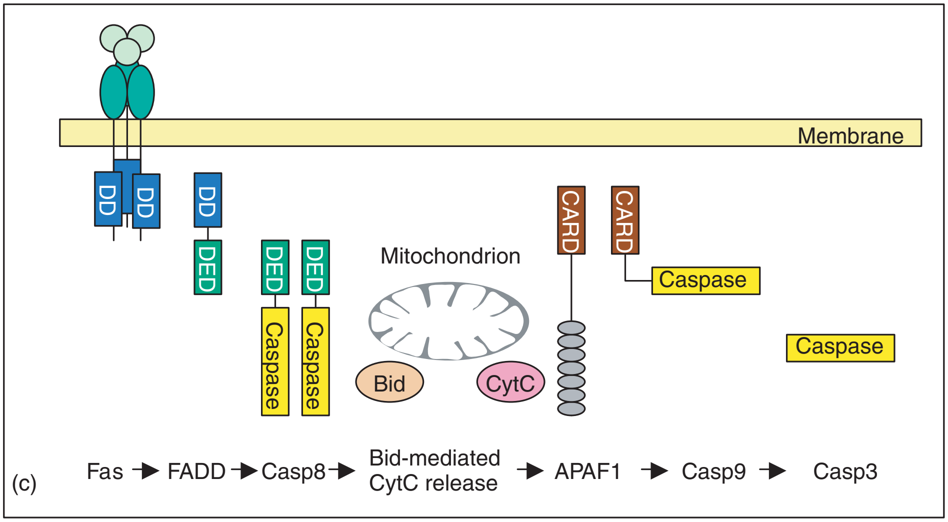

Figure 1 (*continued*)

factors by virtue of their DNA-binding and transactivation domains. Important regulators of this pathway work by selective ubiquitinating and thus downregulating proteins of the cytokine signaling pathway. Similar regulation modes by ubiquitination and selective protein degradation are known in many other signaling pathways as well.

Finally, the signaling pathway from death receptors to cell apoptosis is unusual in that it does not involve protein phosphorylation (Figure 1c) (Wajant, 2003). Central to this pathway is the activation of a protease class, the caspases, by induced proximity (Salvesen and Dixit, 1999). Caspases do not bind directly to the receptors, but rather use a cascade of unique adaptor protein containing domains of the death-domain 6-helix bundle superfamily (Aravind *et al*., 2001; Hofmann, 1999; Hofmann, 2003). Another unusual feature is the liberation of cytochrome C from the mitochondrion as an intermediate signal, which is sensed by the multidomain protein APAF-1. This binding event triggers the downstream branch of apoptosis signaling, which again involves caspases and members of the death-domain superfamily.

2.2. *Proximity activation of enzymes*

One of the recurrent motifs in eukaryotic signal transduction pathways is the activation of enzymes by induced proximity. Enzymatic activities that can be activated by this mechanism include protein kinases and proteases such as caspases. Frequently, these activities are encoded by functional domains, which are brought into close contact by the enzymatically inactive remainder of the protein. As a prerequisite for being susceptible to proximity activation, the enzyme must be inactive in its isolated form, or must be highly specific for a particular substrate to which it normally does not have access. Signaling processes, like for example receptor dimerization, bring two enzyme molecules or two enzymatic domains

into close contact. In the case of caspases, which are synthesized as virtually inactive proenzymes, this close proximity is sufficient for the mutual proteolytic removal of the inactivating prodomain by the very weak residual activity of the two proenzyme molecules (Salvesen and Dixit, 1999). As the caspase prodomains are also responsible for their dimerization, the activated caspases are liberated from the complex. In the case of receptor tyrosine kinases, the two associating kinase domains phosphorylate each other at a position that is not accessible for intramolecular auto-phosphorylation.

2.3. Protein phosphorylation

Protein phosphorylation is probably the most widely used mechanism used in eukaryotic signal transduction (Pawson, 2004; *see also* Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6). The signal itself consists of a phosphate group that becomes attached to the hydroxyl group of a tyrosine, serine, or threonine residue. A large variety of different signals exist, which are distinguished by the nature of the phosphorylated protein and by the site of phosphorylation. Many signaling components can become phosphorylated at multiple positions, sometimes with opposing effects. The phosphorylation signal is generated by protein kinases, whose enzymatic activities are typically encoded by functional kinase domains (see Table 2). Most known kinase domains are evolutionarily related. There are subtle differences between kinases with preference for tyrosine and those preferring either serine or threonine. One group, the so-called dual specificity kinases, are able to modify both tyrosine and serine/threonine residues, their catalytic domains closely resemble the pure tyrosine kinases. Besides the large number of "classical" protein kinases, there also exists a number of different protein domains associated with protein kinase activity (Table 2). Despite their heterogeneity, bioinformatical analyses suggest that all of those domains are distantly related to the canonical protein kinase domains.

Unlike the kinases, which are encoded by recognizable domains, there does not seem to be such a preference for phosphorylatable residues. Most kinases have a preference for certain residues flanking the modified residues, and these conditions appear sufficient to observe phosphorylation in vitro. However, these preferences are far too weak to explain the high phosphorylation specificity observed in vivo. In most cases, a specific substrate recognition by the noncatalytic part of the kinase molecule is required for efficient in vivo phosphorylation. Phosphorylation signals are not necessarily permanent, but can be removed by enzymes belonging to the class of protein phosphatases. In terms of protein relationship, phosphatases are a much more heterogeneous protein class than kinases. A number of different phosphatase domains have been described and are summarized in Table 2.

Besides the mechanisms for generating and terminating phosphorylation signals, cells must have a sophisticated system for the specific recognition of protein phosphorylation; this is typically performed by specialized phosphopeptide-recognition domains (Pawson, 2004; Tsai, 2002). The best known of these domains is the SH2 domain, which recognizes tyrosine phosphorylation. The PTB/PID domain has a similar specificity, but is more rare. The FHA domain seems to

perform an analogous task for the recognition of phosphorylated serine/threonine residues (Table 2).

2.4. Small G-protein signaling

Another important signaling system uses the nucleotide association status of small GTPases of the Ras superfamily (Geyer and Wittinghofer, 1997; Sprang, 1997). This system appears to be optimally tuned for reversibility and hence is frequently referred to as a "molecular switch". Small G-proteins, such as Ras, Rho, Rab, Ran, and others, can associate with either GTP or GDP. In many cellular systems, the GTP-associated form has an activating role, while the GDP-bound form is either inactive or even opposes the role of the GTP-form. Small G-proteins have a very low intrinsic GTPase activity, and without external influences both forms can be stable over a prolonged period of time. An activating signal can be generated by the GDP/GTP exchange factors, which load the small proteins with GTP. This activity is typically encoded by specialized domain classes, each of them responsible for one type of G-protein (see Table 3). Conversely, the activating signal can be terminated by a number of GTPase activating proteins (GAPs). GAP domains specifically bind to their cognate G-proteins and stimulate their intrinsic GTPase activity. Similar to the exchange factors, a particular class of GAP domains acts on each subclass of small G-proteins.

Owing to the large diversity of small G-proteins, there exist a large number of different systems for sensing their GTP/GDP status (Table 3). GTP-associated Ras can be recognized by the RAFRBD domain found in the Raf kinase of the growth hormone signaling pathway (Wittinghofer and Nassar, 1996). The RA domain is distantly related to the RAFRBD and occurs in a large number of Ras effectors. Similar systems exist for other G-proteins, including the Crib domain for Rho/Rac recognition and the RanBP domain for Ran recognition (Table 3).

2.5. Ubiquitination

The covalent modification of proteins with ubiquitin has initially been interpreted exclusively as an earmark for protein degradation by the proteasome. During recent years, however, it has become increasingly clear that protein ubiquitination is used for a variety of signaling purposes, including – but not limited to – different mechanisms for tightly regulated protein degradation (Pickart, 2004). Ubiquitination comes close to, or even surpasses protein phosphorylation in terms of flexibility of the generated signal and also in the number and complexity of signaling components involved (Di Fiore *et al*., 2003) (Table 4). While protein phosphorylation can modify serine, threonine, of tyrosine side chains, ubiquitination is restricted to the ε-amino groups of lysine, and possibly to the protein N-terminus. In contrast to the simple phosphorylation signal, there exists a multitude of ubiquitin-based signal, as ubiquitin itself can be ubiquitinated at various lysine residues, resulting in the formation of poly-ubiquitin chains of different lengths and linkage topologies. There is accumulating evidence that mono-ubiquitin and the different poly-ubiquitin chains all have different signaling capabilities (Schnell and

Hicke, 2003). An additional layer of complexity is provided by several ubiquitin-like modifiers that are distinct from ubiquitin but have similar capabilities for protein modification (Schwartz and Hochstrasser, 2003).

The transfer of ubiquitin and its relatives onto a protein requires a cascade of three enzyme classes termed "ubiquitin activating enzymes" (E1), "ubiquitin conjugating enzymes" (E2) and "ubiquitin ligases" (E3). There are two different classes of E3 enzymes, one of them based on HECT domains, the other one on RING fingers, which are a specific form of complex Zn-finger domains. E3 components clearly harbor most of the diversity, as these components confer specificity to the ubiquitination reaction. Analogous to the phosphatases in kinase signaling, there are a large number of proteases that specifically remove ubiquitin from target proteins (Wing, 2003). Similar to the ubiquitination enzymes, the deubiquitinating activity is typically encoded by dedicated domains, which are surrounded by protein interaction domains conferring target specificity. The ubiquitin signal can be recognized by a number of ubiquitin-sensing domains, the most prominent examples being the UBA, UIM, and CUE domains (Di Fiore *et al*., 2003).

2.6. *Signaling adaptors*

Not all intermediary steps in signal transduction involve the modification of proteins. As exemplified by the death receptor signaling pathway described above, "adaptor proteins" can play a crucial role, in particular, for mediating a controlled amount of pathway cross talk (Hofmann, 1999; Hofmann, 2003). A typical adaptor protein contains two different protein interaction domains, one of them binding to the receptor or another upstream component, and the other one recruiting a downstream signaling component into a "signaling complex".

A prime example is the DISC (for "death inducing signaling complex"), which forms at the cytoplasmic face of death receptors and is crucial for apoptosis signaling (Wajant, 2003). The cytoplasmic tail of death receptors like Fas and TNF-R55 contain a specific six-helix bundle domain termed "death domain" (DD), which has a high propensity to bind to other death domains. This property is used by FADD, a typical adaptor protein that has a death domain binding to the Fas receptor, combined with a "death effector domain" (DED) used for downstream signaling. The DED is distantly related to the death domain, but specifically recognizes other DEDs, but not DDs. The next downstream component, Caspase-8, contains two N-terminal DEDs, which recruit the enzyme to the receptor/adaptor complex, resulting in proximity activation of the caspase (Figure 1c). A third domain class belonging to the same six-helix fold is the "caspase recruitment domain" (CARD), which is found in other adaptor proteins and caspases, which work further downstream in apoptosis signaling. Recently, a fourth class of six-helix interaction domain has been described, the "pyrin domain" (PYD). All four domain classes share the propensity to interact with multiple other domains belong to the same class (Table 5).

Specific protein interactions are also crucial for other signaling events, including the growth factor pathway. For reasons that are not entirely clear, multiple signaling interactions make use of the specific recognition of short proline based motifs by dedicated domain classes, including the intensively studied SH3 and WW

domains (Macias *et al*., 2002; Zarrinpar *et al*., 2003) (Table 5). Although both domain types have similar recognition capabilities, the SH3 domain is prevalent in phosphorylation-based pathways, while the WW domain is more frequent in ubiquitination-based processes.

3. Signaling specificity and complexity

The previous paragraphs have briefly discussed some of the most important domain types found in eukaryotic signaling proteins. Obviously, this domain list is far from being complete. Important signaling systems, such as the heterotrimeric G-proteins and protein domains involved in their regulation have been omitted for space constraints. The same is true for domains that generate or sense small-molecule second messengers. Important examples are adenylate- and guanylate cyclases generating cAMP and cGMP, respectively, and phospholipase C enzymes involved in the generation of inositol- and lipid messengers. Analogous to protein signals, the small-molecule messengers are sensed by effector proteins, which typically also employ modular domains for that task. Several signaling pathways rely on the localization of its components, in particular subcellular compartments, such as the plasma membrane, the nucleus, or even some kind of nuclear body. Protein domains that mediate subcellular targeting, like for example the C2 domain, have also not been discussed.

Finally, one important question should be briefly addressed: If all members belonging to one domain class perform the same unit function, how is the necessary signaling specificity provided? There does not appear to be a general answer applying to all instances. In most cases, the unit function of a domain class is only weakly defined, like for example, “phosphorylation on a tyrosine residue” or “binding to a death domain protein”. There are marked differences between the various tyrosine kinase domains, not only in their sequence but also in their molecular properties. Thus, it is well possible to encode the specificity within the nonessential part of the homology domain. A second source of specificity comes from the use of specific targeting domains. Catalytic domains, which may be quite promiscuous in isolated form, are frequently found in a protein context next to a specificity-conferring protein interaction domain. The possibilities offered by this modular architecture are probably the major reason why the evolutionary shuffling of functional domains in signal transduction systems has turned out to be such a success story.

Short Specialist Review

Sequence complexity of proteins and its significance in annotation

Birgit Eisenhaber and Frank Eisenhaber

Institute of Molecular Pathology, Vienna, Austria

1. Introduction

The concept of complexity of protein sequences originated from the consideration of sequences as strings of symbols that can be studied with linguistic methods. Simple descriptors such as amino acid compositional properties attracted early attention. These studies suggested that small globular proteins can be classified in accordance to amino acid composition and this classification corresponds roughly to secondary structural class, cellular localization, and enzyme function (Nishikawa and Ooi, 1982; Nishikawa *et al*., 1983a; Nishikawa *et al*., 1983b). Nevertheless, the predictive value of this correlation is limited, as later reanalyses with more abundant structural data have shown (Clementi *et al*., 1997; Eisenhaber *et al*., 1996b; Eisenhaber *et al*., 1996a).

With increased efficiency of sequencing in the eighties and nineties of the twentieth century, sequences of multidomain proteins became readily available. Some of their sequence regions differed markedly from previously known globular proteins by obvious abundance of a single or a combination of only very few amino acid types; therefore, these sequence segments were considered “unusual” or “extraordinary”. From the sequence point of view, these compositionally biased regions can be homopolymeric runs, irregular mosaics of a few residue types, or short-period (almost) regular repeats. Genome sequencing projects have shown that such proteins occur frequently, especially in eukaryote proteomes. The fly protein “brakeless” (acc. AAF76322, 2302 AA; its loss of function is associated with unlimited growth of optical axons) is an extreme example. The N- and C-terminal halfs (each of almost 1000 residues) are serine- and glutamine-rich respectively and only three tiny, scattered islands in the middle of the sequence are apparently of globular structure (Senti *et al*., 2000).

The discovery that amino acid compositional bias over domain-size segments is associated with the property of having a globular or nonglobular structure has fuelled the development of criteria for sequence complexity and methods to delineate simple, potentially nonglobular sequence segments as low complexity regions.

2. Criteria for measuring sequence complexity and methods for delineating compositionally biased regions

Whereas sequences from globular domains appear visually as "good" mixtures of residue types, the biased sequence segments are simple because of (1) their nonrandom, highly biased amino acid composition and (2) their tendency of repeating monotonously a small sequence motif. Various methods address these two points but indirect approaches are also possible. Sequence simplicity is often but not always associated with conformational flexibility (invisibility in X-ray structures or only with high B-factor), absence of regular secondary structure (coil status), and high solvent accessibility over long stretches; thus, tools that search for these properties might also be useful to segment a query protein.

The compositional aspect can be evaluated with compositional complexity measures calculated over sequence windows. Given an amino acid composition $\{n_i\}_{i=1,\ldots,20}$ and a sequence window of length $L = \Sigma n_i$, there are $N = L!/\Pi n_i$ possible sequences. In the SEG algorithm (Wootton, 1994a; Wootton and Federhen, 1996), subthreshold segments for the Shannon entropylike term

$$K_2 = -\sum \frac{n_i}{L} \log \frac{n_i}{L} \qquad (1)$$

are searched for and concatenated to a raw region first, after which the subsegment of the raw region with lowest probability $K_1 = \log N/L$ is found. Depending on the window length and thresholds, the sensitivity of SEG can be increased and it can find even regions with subtle compositional deviations such as coiled coil regions.

Other methods such as CAST (Promponas *et al*., 2000) or P-SIMPLE (Alba *et al*., 2002) search for simple segments with bias toward a single amino acid type or a small motif (up to four residues), the first one by assessing alignments with homopolymeric runs and the second by counting motif occurrences in sequence windows. The POPP approach (Wise, 2002) focuses on the frequency of specific mono-, di-, and tripeptides in whole proteins or specified segments and compares them with distributions in sequence databases.

The Globplot tool (Linding *et al*., 2003b) is a propensity-based predictor and the DisEMBL package (Linding *et al*., 2003a) is a suite of neural networks, both parametrized from coil segments in known 3D (three dimensional) structures and can serve for finding extended unordered regions.

Any of the above techniques misses a notable share of nonglobular regions (Kreil and Ouzounis, 2004). With parametrizations for high sensitivity, the false–positive prediction rate is considerable. Thus, uncurated computer-generated annotations of protein sequence databases with these methods are not advisable.

3. Occurrence of compositionally biased regions in protein sequences, their classification, and their role in human disease

It is an early observation that amino acid sequence segments with amino acid compositional bias can occur in natural proteins but, originally, they were

considered exceptional and rare. This view originated from the restricted availability of sequences, mostly of short, single-, or two-domain proteins with well-characterized 3D structure (typically, with metabolic function and of prokaryote origin). Indeed, globular domains with known 3D structure contain a well-balanced composition of various hydrophobic and different polar residues with functional groups. Otherwise, folding with tight packing in the core and a polar, solvatable surface would not have been possible. Not surprisingly, compositionally biased segments are rare in globular domains and comprise only about 0.5% of the sequence (Wootton, 1994b). They are usually short (<30 AA, ∼15 residues on average). Most of the shorter ones appear as moderately polar stretches as part of long solvent-accessible loops or at the polypeptide termini, whereas the longer segments typically represent hydrophobic or amphipatic helices and are involved in the structural packing (Saqi, 1995).

With more efficient sequencing technologies and especially with the genome sequencing projects, the available subset of protein sequences has become more representative. Usually, proteins consist of functionally different sequence regions. Some of them may represent globular domains but the others have compositional bias and, typically, have a nonglobular nature. The amount of low complexity regions in large protein databases has been evaluated with the SEG program and was found to comprise about a quarter of all residues in known proteins. Interestingly, the fraction of low complexity sequence is higher in eukaryotes (an estimated one-third of the total proteome in *Drosophila melanogaster*) compared to ∼10% in prokaryotes (Wootton, 1994b; Wootton and Federhen, 1996; Huynen *et al*., 1998).

The status of structural and functional characterization of low complexity regions is highly diverse. Some examples are listed in Wootton (1994b). Reasonably long spans (often rich in proline and small polar residues) between globular domains apparently serve just as conformationally flexible linkers. Low complexity segments with bias toward hydrophobic residues or with a repetitive hydrophobic pattern are also not so problematic. They are typically found in membrane-attachment regions, are buried in protein complexes, and/or form fibrillar structures.

In contrast, the structure forming potential and the molecular function of long low complexity regions with primarily polar residues remains insufficiently understood. Apparently, many of them carry sites for posttranslational modifications and interactions with other biomacromolecules and are important for cellular regulation and developmental processes (Wootton, 1994b). For example, mutational expansions of CAG triplets coding polyglutamine regions in human genes beyond a certain length cause neurodegenerative disorders such as Huntington's disease, spinocerebellar ataxia 6, or Kennedy disease (Perutz, 2004). Surprisingly, polyasparagine repeats are suppressed in mammalian proteins (Kreil and Kreil, 2000). Many intrinsically unstructured proteins such as titin, prion, tau, and others appear to evolve via repeat expansion (Tompa, 2003).

Polar low complexity regions are especially abundant in the known part of the proteome from *Plasmodium falciparum*, *Plasmodium berghei*, and *Dictyostelium discoideum* – even relative to the background of other eukarya (Pizzi and Frontali, 2001). Possibly, variable immuno-dominant epitope loops of transmembrane proteins and the variety of glycosylation variants in polyasparagine tracts have

clinical relevance since they are part of *Plasmodium*'s strategy to evade the immune response of the host (Duffy *et al*., 2003; Newbold, 1999).

The strict criteria for selecting low complexity segments in standard tools overlook many instances of regions with milder compositional bias that are nevertheless not globular either. The environment of sites for many posttranslational modifications (PTM) and subcellular translocation signals are examples of the more general theme of interaction of a globular protein with an extended and conformationally malleable region of another one (Eisenhaber *et al*., 2004; Iakoucheva *et al*., 2004). In the case of a PTM, only a small region of the binding site of the substrate protein directly interacts with the active site cavity of the modifying enzyme. To allow this interaction physically, the site of the PTM has to be surrounded by a sufficiently solvent-interacting sequence region without own inherent conformational preferences that links the site of the PTM with the remainder of the substrate protein (Eisenhaber *et al*., 2004).

4. The homology concept and the role of compositionally biased regions in sequence similarity searches

The most successful and widely known approach for inferring protein function with nonexperimental means, the annotation transfer from homologs, is based on the observation of similarity between protein sequences having similar 3D structure and molecular function. In evolutionary terms, even distantly related sequences are considered to originate from a common ancestor sequence in a mutational process.

The distance metrics used in sequence similarity searches, for example, the E-values in the popular BLAST/PSI-BLAST suites (Altschul *et al*., 1994; Altschul *et al*., 1997) that evaluate the probability of having a common ancestor, are correctly applicable only for globular sequence segments. The amino acid type substitution matrices such as BLOSUM62 (Henikoff and Henikoff, 2000) are derived from datasets of point mutations in secondary structural elements in globular domains of well-studied protein families and are, therefore, designed to detect subtle sequence similarities between distantly related sequence instances of the same family. Not surprisingly, false–positive hits in database searches are typically caused by compositionally biased regions, for example, cysteine- or proline-rich regions, long hydrophobic stretches of transmembrane helices/signal peptides or monotonous hydrophobic patterns of fibrillar structures.

Hence, it is necessary to remove compositionally biased regions from query sequences before sequence similarity searches. As a standard option, BLAST offers the most stringent standard parametrization of the SEG program for masking obviously low complex segments. Especially in the case of frequently interspersed homopolymeric runs, CAST is a good alternative (Kreil and Ouzounis, 2004). Often, both approaches are insufficient to remove the cause of collecting false hits and it becomes necessary to carefully determine membrane-embedded regions, fibrillar segments, peptides that are responsible for targeting to subcellular localizations (for example, signal peptides), regions responsible for posttranslational modifications (Eisenhaber *et al*., 2003; Nielsen *et al*., 1999), and other types of nonglobular segments in the query prior to the similarity search.

Short Specialist Review

Protein repeats

Carolina Perez-Iratxeta and Miguel A. Andrade

Ottawa Health Research Institute, Ottawa, ON, Canada

1. Definition

Some protein domains are composed of units of similar structure (see Figure 1). Often, but not always, these units are also similar in sequence, which explains why they have a similar structure. Therefore, they can be considered protein repeats that originated by duplications from a single ancestral sequence.

These small units are large enough to form secondary structural elements but too small to be stable by themselves. They acquire stability by folding together in a repetitive structure. This is the defining feature of protein repeats. They occur repeated, never alone.

Repeats tend to be tandemly repeated (one next to the other in sequence), but the occurrence of insertions of variable length in between repeats is sometimes observed. Those insertions tend to lack structure and to be short, although there seems to be no obvious reason for that. We can speculate that because folding of a structure composed of repeats is more delicate than that of globular folds, large insertions would make the fold unstable or difficult to form.

Since repeats are consecutive in sequence, a condition on their structure is that the C-terminal must be spatially near the N-terminal in order to produce units that can fold together in a compact continuum of repeat units. Given the fact that the elements of secondary structure are quite linear, a repeat must contain a minimum of two of them to bring the C-terminal of the repeat close to the N-terminal. This imposes a minimum length of about 12 amino acids on these repeats. An upper bound of about 50 amino acids can be explained because a larger unit could fold into an independent domain that does not need another repeat to form a stable fold.

2. Classification

Repeats can be classified, like protein folds, depending on the secondary structural elements that compose them. Accordingly, most widespread repeats can be grouped in three groups, all-alpha, all-beta, and alpha/beta:

- Armadillo/HEAT repeats and tetratricopeptide repeats (TPR-like) in the all-alpha group.

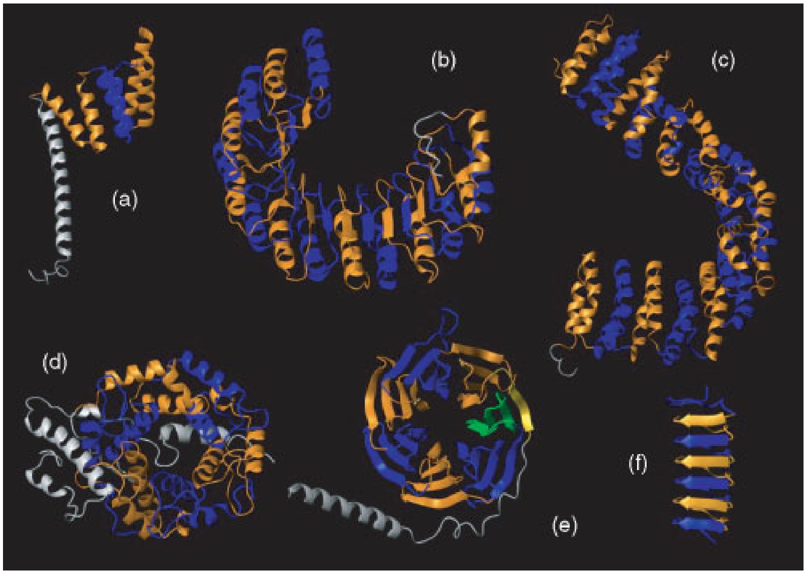

Figure 1 Examples of protein domains composed of repeats. (a) TPR repeats (PDB id: 1a17). (b) Leucine-rich repeats (PDB id: 1dfj, chain I). (c) HEAT repeats (PDB id: 1b3u). (d) PFTA repeats (PDB id: 1ft2, chain A). (e) WD40 repeats (PDB id: 1gp2, chain B). (f) Beta-loop repeats in an antifreeze protein (PDB id: 1ezg). Blue and orange represent alternating repeats. The rest of the structure is colored in grey. In the case of WD40 (e), one of the repeats is composed of a beta strand (in yellow) previous to the first repeat and three C-terminal beta strands (in green); this way of closing a barrel composed of beta-sheets is observed in other protein families of similar structure. The figure was composed using the MOLMOL software (Koradi *et al*., 1996)

- Beta propellers (as WD40 and Kelch) and beta trefoils in the all-beta group.
- Leucine-rich repeats (LRR) and ankyrin repeats in the alpha/beta group.

There are many more repeat families that occur less frequently (Andrade *et al*., 2001a), such as the beta-loop 12-residue repeats found in an insect antifreeze protein.

The shape of the superstructure can also define the function and dynamics of the repeat unit and, therefore, must also be taken into account. Repeats can form open structures (see examples in Figures 1a, 1b, 1c, and 1f) or closed structures (see examples in Figures 1d and 1e). Open structures formed by repeats are observed with variable copy number, whereas close structures are more constrained to a copy number appropriate to the closing of the superstructure (Andrade *et al*., 2000).

3. Structure and function

In general, domains composed of repeats confer to proteins an enlarged binding surface area with the possibility of multiple binding and structural roles. This is the reason protein–protein interaction is the most prevalent function of proteins with repeats (Andrade *et al*., 2001b). The periodicity of the three-dimensional structure

favors spatially periodic or symmetric interactions that are critical for structural integrity in various cellular contexts (for example, spectrin in the submembrane lamina or HEAT repeats in the vesicular coat structures). Among other functions performed by proteins with repeats, we can find enzymatic activities, ice binding (in antifreeze proteins), or energy storage proteins in plant seeds.

4. Evolution and distribution

Repeats have appeared multiple times along evolution. They originate by duplication and recombination within a single gene. The evolution of repeats from a common ancestor that necessarily must have contained a single repeat seems paradoxical, given that apparently more than one repeat is required for folding. One possible explanation is that the ancestor formed homo-oligomers where two identical chains provided the repetition (Ponting *et al*., 2000).

It is estimated that 14% of all proteins have repeats (Marcotte *et al*., 1999). Their actual number is probably higher, because the estimate is based on sequence comparison, and therefore missing those that have no detectable sequence similarity.

Repeats are present over all taxa but are more abundant in eukaryotic organisms and among them most frequent in metazoans. This distribution shows a correlation between the increase of organism complexity and the already mentioned principal function of domains composed of repeats, binding proteins.

5. Detection

Identifying tandem repeats with high sequence similarity is relatively easy. However, it happens that the constraints in sequence conservation among repeats are relatively lax. For example, the HEAT repeats of the structure displayed in Figure 1c average only 18% of sequence identity. Their short length complicates their detection too, and the number of repeats per protein may differ between members of the same family. In the absence of a reference structure, it is especially difficult to detect the boundaries of each repeated unit. Several methods have been published dealing with the detection and analysis of repeats (REP, **http://www.embl.de/~andrade/papers/rep/search.html**, Andrade *et al*., 2000; REPRO, **http://ibivu.cs.vu.nl/programs/reprowww/**, George and Heringa, 2000; Pellegrini *et al*., 1999).

Short Specialist Review

Large-scale protein annotation

Sarah K. Kummerfeld
MRC Laboratory of Molecular Biology, Cambridge, UK

1. Introduction

A bacterial genome encodes anywhere between 500 and 5000 proteins, whereas a large eukaryotic genome encodes as many as 25 000 proteins. Making sense of a whole-genome set of amino acid sequences may sound like a daunting task; if your approach were to consider each protein in turn through literature review and traditional experimental biochemistry, you would be right to be worried. However, computational approaches have been developed to allow automatic prediction of structure, function, and evolutionary relationships from amino acid sequence data.

This review provides an overview of large-scale computational techniques and databases by tracing the annotation of a hypothetical proteome. Our approach uses catalogs of experimentally determined protein annotation and homology methods to accurately annotate as much of the proteome as possible. Finally, we discuss how whole-proteome annotation is being used to address novel biological questions.

2. Catalogs of experimentally determined protein annotation

To begin our hypothetical proteome annotation, suppose we are given 5000 polypeptides derived from genome sequencing and gene prediction of our genome of interest. A first step is to annotate proteins for which we have experimentally derived information. Increasingly, databases are being established to store details about protein structure and function in a way that can be automatically searched.

The main repository for experimentally determined structures is the Protein Data Bank (PDB) (**http://www.rcsb.org/pdb/**, Berman *et al*., 2000), which included almost 30 000 structures at the time of writing. For functional annotation, there are many experimentally derived databases. These differ in the taxonomic source or functional class of the proteins they include and the type of experiments used to obtain the functional information.

One of the largest databases of functional annotation for proteins from across all kingdoms of life is SwissProt (**http://us.expasy.org/sprot/**, Boeckmann *et al*., 2003). Where available, annotation includes details about each protein's function, posttranslational modifications, structure, domains, similarity to other proteins, and associated diseases. There are also many system- or genome-specific catalogs

including Drosophila genome database, FlyBase (**http://flybase.bio.indiana.edu/**, The FlyBase Consortium, 2003), Biochemical pathway database, EcoCyc (**http://ecocyc.org/**, Karp *et al*., 2002), Kyoto Encyclopaedia of Genes and Genomes (**http://www.genome.jp/kegg/**, Kanehisa, 1997), which includes a comprehensive section on pathways and signal transduction, BIND biomolecular interaction network database for protein interactions (**http://bind.ca/**, Bader *et al*., 2003), and Online Mendelian Inheritance in Man for human disease genes (**http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM**, McKusick, 1998).

An example of a higher-level functional annotation is the GeneOntology database (GO) (**http://www.geneontology.org/**, The Gene Ontology Consortium, 2000). GO provides a treelike functional hierarchy, with mappings to various protein annotation databases, for example, FlyBase and PDB. The hierarchy provides a common language for comparison between species or datasets that individually have different systems of annotation.

Directly searching structural and functional databases described above would yield annotation for a small subset of the 5000 sequences in our proteome of interest; representing proteins that had been experimentally characterized before the genome was sequenced. These annotations would be expected to be extremely accurate as they are limited only by the representation of the data in the database and experiments themselves. However, this leaves the majority of proteins unannotated. The next section describes how we can use homology to predict the structure and/or function of proteins for which no experimental results are available.

3. Homology methods for annotation

Proteins with very similar amino acid sequence tend to adopt a similar fold and consequently have similar functions. This principle is used to infer structure/function by homology: proteins with no known structure/function are compared with proteins from experimentally characterized catalogs. In cases where the unknown protein is matched as being similar to one in the characterized set, we can infer that their structures and/or functions are similar. This is the principle for the protein annotation part of many genome annotation systems, for example, the Ensembl analysis pipeline (Potter *et al*., 2004). In this section, we outline a standard set of methods that may be used by an annotation pipeline.

There is a large range of methods that can be used to assess homology. One of the simplest is pairwise sequence comparison using a program such as BLAST (Altschul *et al*., 1990) or FASTA (Pearson and Lipman, 1988). Returning to our hypothetical proteome, we consider each protein in turn as a query sequence, and we use BLAST to search against the catalogs of experimentally characterized proteins as the database. BLAST returns a list of matches between our query and the database, indicating the likelihood that this match occurred by chance. For example, by comparing each protein from our set of 5000 with the SwissProt functionally characterized proteins, we are able to predict the function for all the proteins that have significant matches to a SwissProt annotated protein. These database searches are fast and allow immediate inference of structure or function for proteins with a characterized homolog.

Pairwise sequence comparison can also be used to assess the evolutionary relationship between proteins in our set and other proteomes. For example, searching each of the 5000 proteins in turn with BLAST against a database containing the proteomes of three closely related organisms will allow identification of orthologs and paralogs between the genomes. There are purpose-built tools to perform these evaluations including INPARANOID (**http://inparanoid.cgb.ki.se/**, Remm *et al*., 2001) for prediction orthologs and Clusters of Orthologous Groups (**http://www.ncbi.nlm.nih.gov/COG/**, Tatusov *et al*., 1997) for grouping functionally related paralogs.

While the details of pairwise sequence comparison are beyond the scope of this review, it is important to understand that as a method of homology detection, pairwise sequence comparison is only useful for detecting relatively close homologs. Even if two proteins adopt an identical fold and function, BLAST will not recognize them as homologs if their protein sequences are sufficiently different. A second set of homology methods uses sequence profiles to match structurally homologous proteins with lower sequence similarity than would be possible to identify with BLAST. Instead of comparing the query sequence to a sequence database, profile methods compare the query to a set of profiles. Profiles are based on alignments of closely related sequences; they indicate the probability that each amino acid should occur at a particular position in the sequence. This effectively encodes the underlying information about the conservation pattern across an entire group of related proteins, and provides a model that allows detection of more divergent homologs.

Some of the most extensive domain profile databases are Pfam (**http://www.sanger.ac.uk/Software/Pfam/**, Bateman *et al*., 2004), SUPERFAMILY (**http://supfam.org**, Gough *et al*., 2001), ProDom (**http://protein.toulouse.inra.fr/prodom/current/html/home.php**, Corpet *et al*., 2000), and Tigrfams (**http://www.tigr.org/TIGRFAMs/**, Haft *et al*., 2003). They can be used to identify functionally relevant and evolutionarily conserved sequence features as well as globular domains in proteins. The Pfam database provides a curated multiple sequence alignments for functional domain families. Using the HMMER (**http://hmmer.wustl.edu/**) sequence-profile search software, it is possible to search each of our 5000 sequences against the library of profiles. This generates a list of regions where the query sequence has a significant match to a particular domain family profile. Similarly, the SUPERFAMILY database provides profiles for structural, evolutionary-related domains. Probabilistic models are also used for the prediction of signal peptides in SignalP (**http://www.cbs.dtu.dk/services/SignalP/**, Bendtsen *et al*., 2004) and transmembrane helices in TMHMM (**http://www.cbs.dtu.dk/services/TMHMM/**, Krogh *et al*., 2001). The predicted location of Pfam (functional) domains, SUPERFAMILY (structural/evolutionary) domains, signal peptides, and transmembrane helices further contribute to the annotation of our proteome.

As with pairwise sequence comparison, profile methods can tell us a lot about the evolutionary history of proteins. In particular, a database such as SUPERFAMILY, whose domain definition is based on evolution, allows comparison of the domain repertoire of different proteomes.

The final type of database that we will discuss is based primarily on patterns. Examples include PROSITE (**http://us.expasy.org/prosite/**, Hulo *et al*., 2004) and

PRINTS (**http://bioinf.man.ac.uk/dbbrowser/PRINTS/**, Attwood *et al*., 2003). Rather than grouping homologous domains or proteins, these databases include motifs or patterns that have a particular functional role. For example, PROSITE patterns indicate biologically important functional sites. The results of searching for these patterns in our set of 5000 proteins can then be added to the functional annotation.

4. Interpreting whole-proteome annotation

Having used homology methods to infer the structure and function for as many proteins in our set of 5000 as possible, this leaves us asking: what does this tell us? Now that we have a wealth of functional, structural, and evolutionary information, we can begin to ask questions about the biology of our newly sequenced genome and how it compares with other organisms. Here we present two examples of biologically important discoveries that have been made on the basis of annotation from freshly sequenced proteomes: assessment of a newly sequenced organism's potential as a model system and exploring the evolutionary relationship of protein domains.

Identifying model organisms to study human diseases is a fundamental step in medical research. *Dictyostelium discoideum*, slime mold, has long been held up as a useful experimental system because it is relatively simple to work with, but has features that are not found in early-branching eukaryotes, including complex signal transduction, pattern formation, phagocytosis, and some aspects of development. On completion of the genome sequence, the proteome was annotated (using a similar procedure to our hypothetical example), providing a parts list of domains present in the proteome. The Pfam domain assignments, serving as a functional annotation, were used to carry out a protein-level comparison between Dictyostelium and other eukaryotes. This allowed identification of proteins common to Dictyostelium and animals, including domains related to signaling and cell adhesion. The proteins found to have these higher-eukaryote-like domains are now candidates for use as experimental systems to study intercell signaling and adhesion.

A second example of interpreting large-scale protein annotation data aims to understand how modular proteins have evolved. A recent study (Vogel *et al*., 2004) compared the patterns of domains found in 131 completely sequenced genomes. By considering the N-C terminal arrangement of domains, Vogel *et al*. found that particular two and three domains patterns are overrepresented. Using confirmation from structural information, they were able to show that these groups of domains are themselves evolutionary units, termed "supradomains", which have been duplicated as a set. Not only did this study extend our understanding of how proteins have evolved, it also provided a list of high-priority targets for structural genomic projects. Since supradomains are overrepresented, solving structures for representatives will significantly increase structural coverage of protein space.

Large-scale computational protein annotation provides feasible methods for predicting the structure, function, and evolutionary history of proteins from their amino acid sequence. Using remote homology detection methods, we can make accurate (less than 1% error) predictions about the domain structure of between 30

and 80% of proteins in individual genomes and 60% of proteins in the UNIPROT database. Experimentally determined functional annotation is available for a smaller fraction of proteins; through homology, this information can be applied to whole genomes. Current genome annotations are sufficient to answer questions about the biology of whole organisms, their systems, and evolutionary relationships.

Measuring evolutionary constraints as protein properties reflecting underlying mechanisms

Andrew F. Neuwald
Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, USA

Jun S. Liu
Harvard University, Cambridge, MA, USA

1. Introduction

Certain protein families are very highly conserved across the major divisions of life. This is illustrated, for example, by the alignment in Figure 1(a) of Ran GTPases, which demonstrate a remarkable degree of sequence conservation across metazoans, fungi, plants, and protozoans. Ran is a member of the Ras superfamily of small GTPases (Hall, 2000), which function as molecular binary switches involved in cellular signaling pathways. Ran's specific role involves signaling subcellular location with reference to chromosomes and the nucleus (for a recent review, see Quimby and Dasso, 2003).

Inasmuch as proteins such as Ran are highly conserved and appear to be required by all eukaryotes, these constitute the core of the eukaryotic cellular machinery, and thus have more or less ceased to evolve one to two billion years ago. The functions of most of the highly conserved residues in such proteins are unknown, yet clearly important, considering that often even minor modifications, such as side-chain attachment of a methyl or hydroxyl group, are consistently eliminated by natural selection. Indeed, at some residue positions (e.g., 75 and 81 in Figure 1a), even isomeric swapping between leucine and isoleucine is strongly selected against. Such residues are likely to form functionally critical interactions with specific geometric and/or chemical constraints corresponding to subtle and currently poorly understood principles.

Much of our understanding of the principles of protein function comes through biophysical, biochemical, and genetic analyses, which reveal basic properties, such as sequence, structure, catalytic activity and kinetics, and subcellular location. Likewise, conserved patterns in multiple sequence and structural alignments constitute another important source of biological information inasmuch as these reflect selective constraints imposed by the underlying mechanisms during protein evolution.

Indeed, these selective constraints – as quantified through statistical analysis of co-conserved patterns (see below) – may be viewed as basic properties of proteins.

Interpreting the biological significance of conserved patterns is confusing, however, when nearly all residues in a protein family are well conserved, as for Ran. In this case, it is helpful to first decompose conserved residues into functional

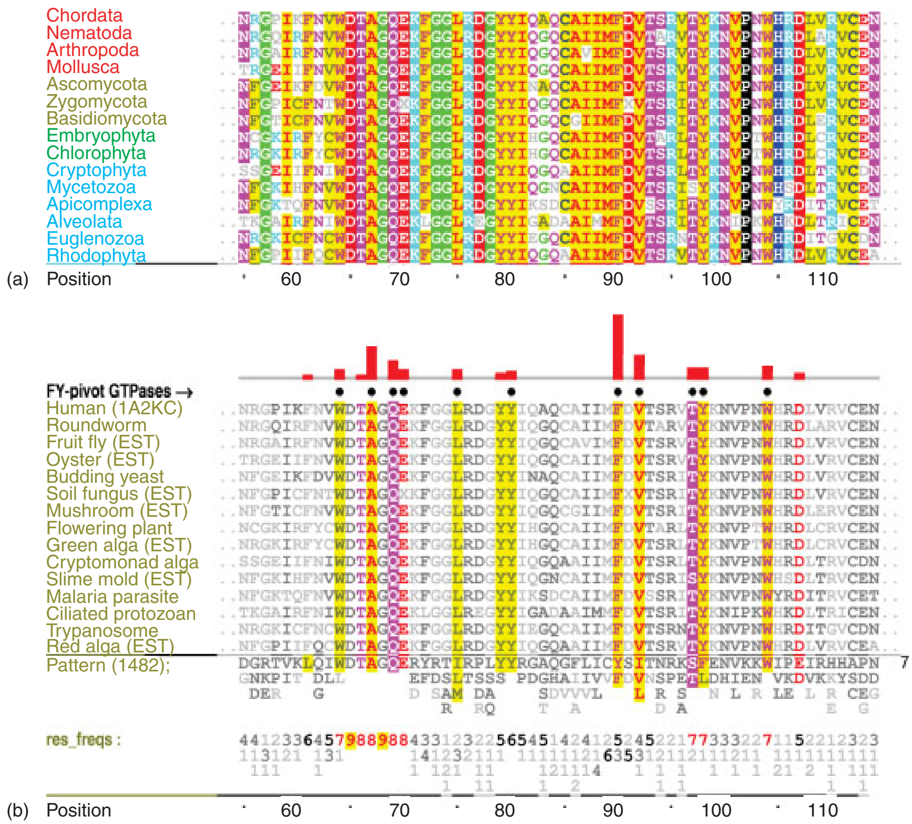

Figure 1 (a) Ran family multiple alignment. The leftmost column specifies each sequence's phylum, which are colored by major eukaryotic taxa as follows: metazoans, red; fungi, dark yellow; plants, green; protozoans, cyan. Only a subregion of the Ran alignment is shown. The top sequence is the query. (b) CHAIN analysis Ran family contrast hierarchical alignment. Ran family aligned residues are displayed directly, while the "foreground" sequences (as defined in the text) consists of FY-pivot GTPases, which are too numerous to display directly and thus are represented below the alignment as position-specific conserved patterns. (The total number of aligned sequences is shown in parentheses.) The corresponding residue frequencies ("res_freq") are given in integer tenths below the conserved patterns. For example, a "5" in integer tenths indicates that the corresponding residue directly above it occurs in 50–60% of the (weighted) sequences. Histogram bar heights are approximately logarithmically proportional to our measure of selective constraints, as defined by a ball-in-urn statistical model at each position in the alignment. This model defines the selective constraint as the difficulty of drawing by chance at least as many of the same or similar balls (residues) from a given position in an alignment of all P-loop GTPases as are observed at that position for FY-pivot GTPases. Dots below the histogram (and directly above the alignment) indicate residue positions specifically assigned to the FY-pivot category. (c) Contrast hierarchical alignment showing co-conserved residues in various FY-Pivot GTPase families of known structure. The leftmost column gives the pdb code and protein name. (Reproduced from Neuwald *et al*. (2003) by permission of Cold Spring Harbor Laboratory Press)

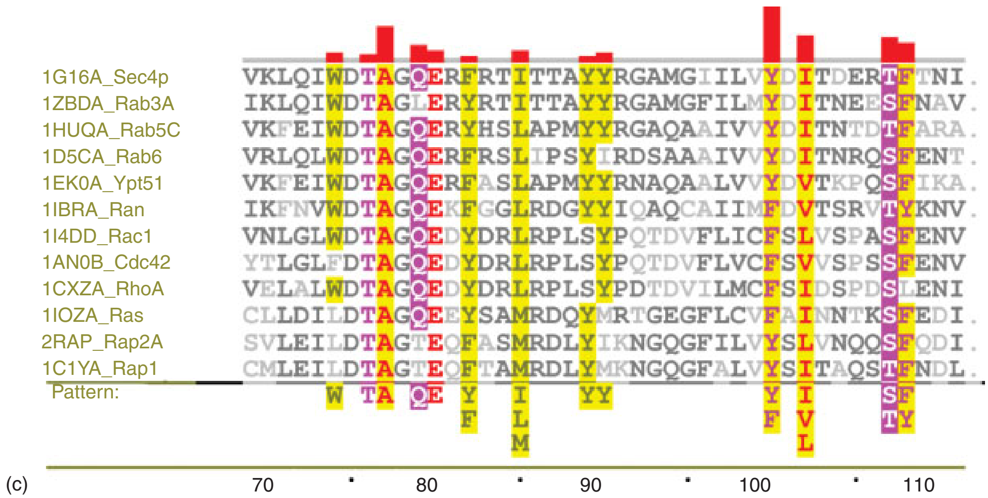

Figure 1 (*continued*)

categories on the basis of their patterns of conservation within a large class of homologous proteins. Identifying residues in Ran involved in nucleotide binding and hydrolysis is straightforward, as these are highly conserved across all P-loop GTPases. The functions of residues with more complex patterns of conservation, however, are less easily ascertained.

2. CHAIN analysis

Contrast hierarchical alignment and interaction network (CHAIN) analysis (Neuwald *et al*., 2003) identifies groups of optimally co-conserved residues and corresponding molecular interactions. Such co-conserved patterns presumably correspond to category-specific functional constraints that are "layered on top of" the weak constraints maintaining that protein's structural fold – which may be conserved in the absence of detectable pairwise sequence similarity (*see* Article 72, **Threading for protein-fold recognition**, Volume 7). CHAIN analysis works best on proteins belonging to a large class consisting of many well-conserved families and subfamilies and for which vast amounts of sequence, structural, and other experimental data are available. In this case, powerful statistical procedures can be used to accurately align the sequences and to detect subtle, yet biologically significant characteristics.

CHAIN analysis was initially applied to Ran and related small GTPases (Neuwald *et al*., 2003). This revealed a group of co-conserved residues (Figure 1b,(1)c) and structural interactions (Figure 2) within Rab, Rho, Ras, and Ran GTPases, which were termed FY-pivot GTPases after a strikingly conserved phenylalanine or tyrosine that appears to serve as a pivot. Because these residues are strikingly *unconserved* in other GTPases (including the Ras-like GTPases Arf and Sar), they presumably perform a function specific to FY-pivot GTPases. Moreover, these

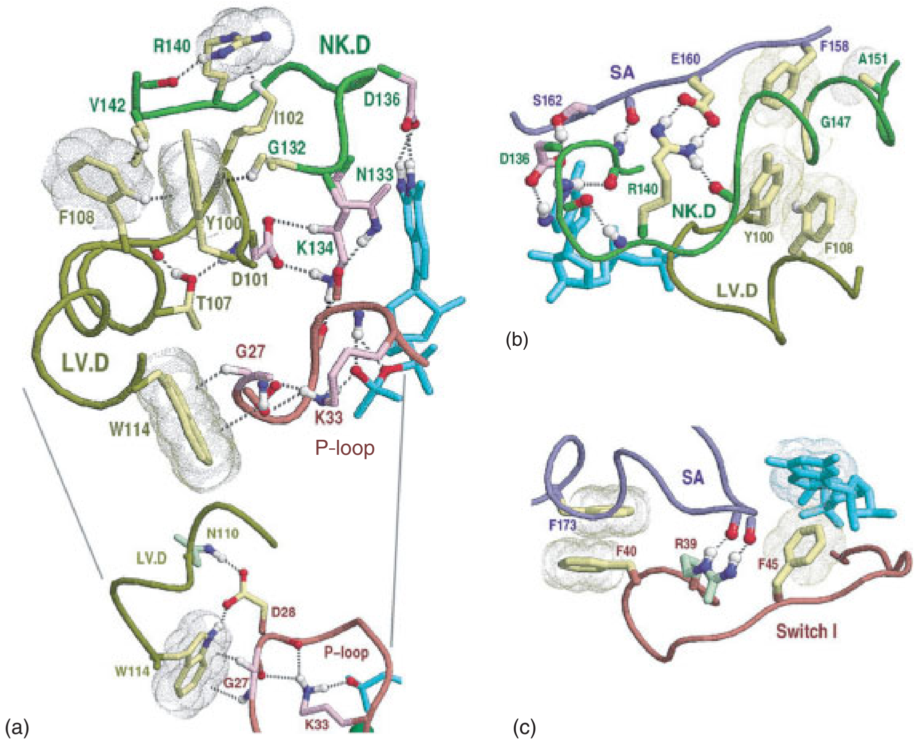

Figure 2 Sec4p as a structural prototype of FY-pivot GTPases. The structure of Sec4p is shown in complex with GDP (pdb code: 1G16) (Stroupe and Brunger, 2000). Hydrogen bonds are depicted as dotted lines, and aromatic–aromatic and van der Waals interactions as dot clouds. Dotted lines into clouds depict CH-π or NH-π hydrogen bonds (Weiss *et al*., 2001). Color scheme: GDP (cyan); main-chain traces and residue designations (colored by regions); residue side chains and canonical glycine main chains (yellow, co-conserved in FY-pivot GTPases; magenta, conserved in all GTPases; green, intermediate); oxygen, nitrogen, and hydrogen atoms establishing hydrogen bonds (red, blue, and white, respectively); hydrogen bonding carbons (colored as their corresponding side chains) (Reproduced from Neuwald *et al*. (2003) by permission of Cold Spring Harbor Laboratory Press). (a) Residues surrounding the P-loop. (b) Residues near the FY-pivot (Y100). (c) Residues in the Switch I region

residues, along with other residues specifically conserved in Ran (not shown), appear to play important roles in Ran nucleotide exchange (Neuwald *et al*., 2003). Rather than focusing on the biological implications of this and similar analyses, however, which are described in detail elsewhere (Kannan and Neuwald, 2004; Neuwald, 2003; Neuwald *et al*., 2003), this article focuses on the methodological aspects of CHAIN analysis.

3. A mathematical description of selective constraints

Although qualitative descriptions can be useful, mathematically rigorous descriptions reveal subtle properties that otherwise would be missed. For this reason, CHAIN analysis defines protein-selective constraints on the basis of classical and

Bayesian statistical models. Conceptually, these formulations are roughly analogous to the notion of free energy in statistical thermodynamics: Just as the energy of a chemical reaction may be defined by the degree to which products have shifted away from reactants, CHAIN analysis defines selective constraints by the degree to which residue positions in a subset of aligned homologous sequences (termed the foreground set) have shifted away from (or contrast with) the residue compositions observed at those positions in the remaining sequences (termed the background set). This is illustrated for Ran in Figure 1(b).

Put another way, just as ΔG defines the difference in free energy between distinct thermodynamic states, our statistical models define differences in selective constraints between two distinct protein "functional states": those corresponding to the foreground and background sets. CHAIN analysis optimally defines the foreground and background sets using a Gibbs sampling (Liu, 2001) procedure called Bayesian partitioning with pattern selection (BPPS) (Neuwald *et al*., 2003). This procedure defines a foreground set such that these sequences share a strikingly conserved pattern that is strikingly unconserved in the remaining, background sequence set (Figure 3).

The input alignment may be defined in various ways depending on the nature of the selective constraints one seeks to characterize. For example, when analyzing an active ATPase, one may choose to remove inactive homologs from the input alignment while retaining active ATPases. (This may be done using certain CHAIN analysis routines, including the BPPS procedure itself.) Indeed, the most useful information is obtained by measuring and comparing selective constraints associated with biologically meaningful foreground and background "states" in this way. Thus, just as a chemist describes a protein's physical properties by measuring changes in free energy between various thermodynamic states, the BPPS procedure describes a protein's evolutionary properties by measuring changes in selective constraints between various functional categories.

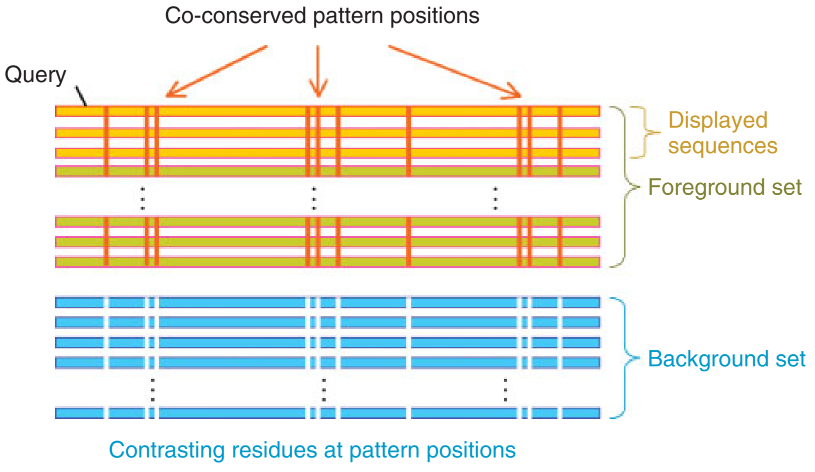

Figure 3 Schematic representation of a "contrast hierarchical alignment" generated by the BPPS procedure. See discussion in text

4. Analogy between CHAIN analysis and protein crystallography

Algorithmically, CHAIN analysis infers information about underlying protein mechanisms from conserved sequence and structural patterns in a manner analogous to inferring protein structural information from crystalline X-ray diffraction patterns (Figure 4). Moreover, as is true of crystallography, CHAIN analysis is empirical inasmuch as it models selective constraints based solely on what may be justified statistically by the input data. It lets the data speak.

The first step (analogous to protein purification) is to apply iterative search procedures – which, in large part, are based on the PSI-BLAST algorithm (Altschul *et al*., 1997; *see also* Article 93, **Detecting protein homology using NCBI tools**, Volume 8) – to gather many, often distantly related protein sequences and corresponding available structures. For enhanced search sensitivity, CHAIN analysis also may rely on profile hidden Markov models (HMMs) (Eddy, 1998; *see also* Article 98, **Hidden Markov models and neural networks**, Volume 8) applied in conjunction with Markov chain Monte Carlo (MCMC) optimization methods (Neuwald and Liu, 2004; Neuwald and Poleksic, 2000).

The second step (analogous to crystal formation) is to multiply align the sequences and structures very precisely in order to identify biologically meaningful co-conserved patterns. CHAIN analysis currently multiply aligns (often thousands

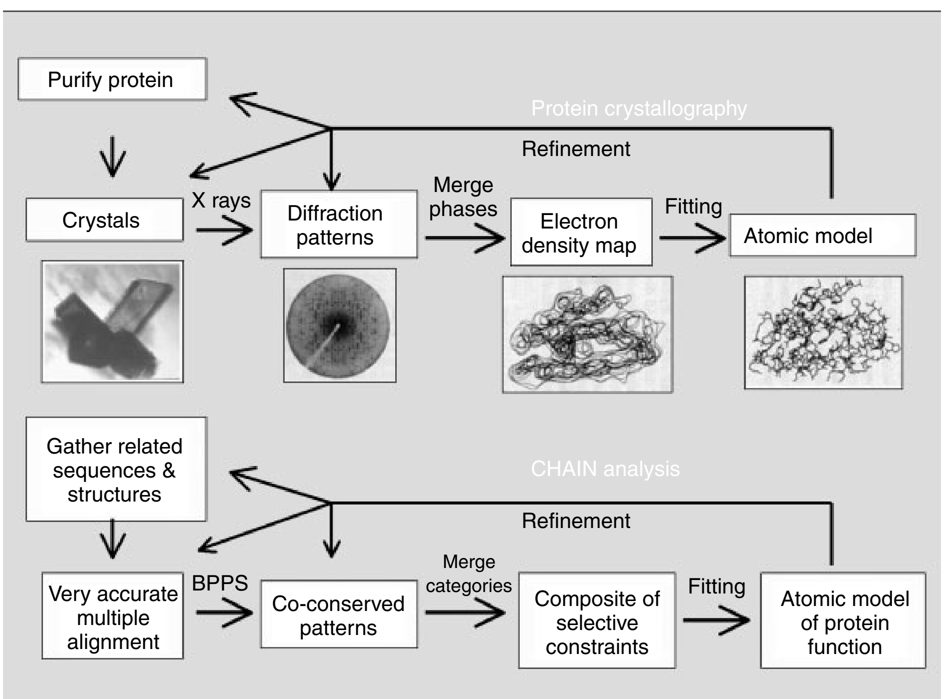

Figure 4 Analogy between CHAIN analysis and protein crystallography. See discussion in text

or tens of thousands of) sequences using a modified version of the PSI-BLAST algorithm that incorporates statistically based HMM and MCMC sampling strategies (Neuwald *et al*., 2003; Neuwald and Liu, 2004; Neuwald and Poleksic, 2000) that are extensions of our earlier Gibbs sampling methods (Lawrence *et al*., 1993; Liu *et al*., 1995; Liu *et al*., 1999; Neuwald *et al*., 1995; Neuwald *et al*., 1997; *see also* Article 106, **Gibbs sampling and bioinformatics**, Volume 8). These statistical procedures help correct misaligned regions, such as those associated with protein domains harboring sizable insertions. Unlike most multiple alignment methods, all of these methods align sequence regions only when there is statistical support for evolutionary conservation – an essential characteristic for accurately estimating selective constraints. CHAIN analysis also relies on programs, such as CE (Guda *et al*., 2004; Shindyalov and Bourne, 1998), for structural alignment (*see* Article 75, **Protein structure comparison**, Volume 7), which – though often viewed as a gold standard – can also introduce errors owing, for example, to rotation of homologous substructures relative to each other. For this reason, "intervention strategies" (Neuwald and Liu, 2004) that can tap into expert knowledge provided by the user, yet still rely on objective statistical criteria to assess alignment quality, are also employed.

The third step (analogous to gathering X-ray diffraction patterns) involves repeated application of the BPPS procedure (Neuwald *et al*., 2003) (see above) to optimally define multiple categories of co-conserved patterns. For each of these categories and at each pattern position, a classical ball-in-urn statistical model is used to quantify selective constraints relative to the background set (Figure 1b, 1c).

The fourth step (analogous to constructing an electron density map) is to merge various categories of selective constraints into a composite picture of the entire protein class. Within a specific protein family, this often reveals a hierarchy of increasingly specialized co-conserved functional "components" that presumably arose through a process of evolutionary divergence and specialization. Such components appear to be layered, so to speak, one on top of another and to function together in a coordinated manner. Comparing and contrasting the hierarchical characteristics of various members of a class provides a global perspective of the selective constraints acting on each protein and on the class as a whole. It is also helpful to analyze in the same way those proteins that functionally interact with the proteins of interest.

The fifth step is to "fit" the various categories of selective constraints to other available experimental data in order to identify likely molecular mechanisms associated with the protein class. Conceptually, the fitting is done probabilistically rather than deterministically, as is illustrated by the Venn diagram in Figure 5. Each point within the Venn diagram represents a possible mechanistic model, while each circle represents a set of high-probability models given the indicated data source. For example, the currently available biochemical data weighs in favor of some models, disfavors others, and totally excludes others still. In principle, by combining these sources of data (using bioinformatics tools) with inferred evolutionary constraints, one may identify those models that are most compatible with the available data (i.e., the area labeled "high-probability models" in Figure 5). Ideally, we would like to represent all of these data sources using rigorous Bayesian statistics, just as we have done for estimating selective constraints within sequences. Though this

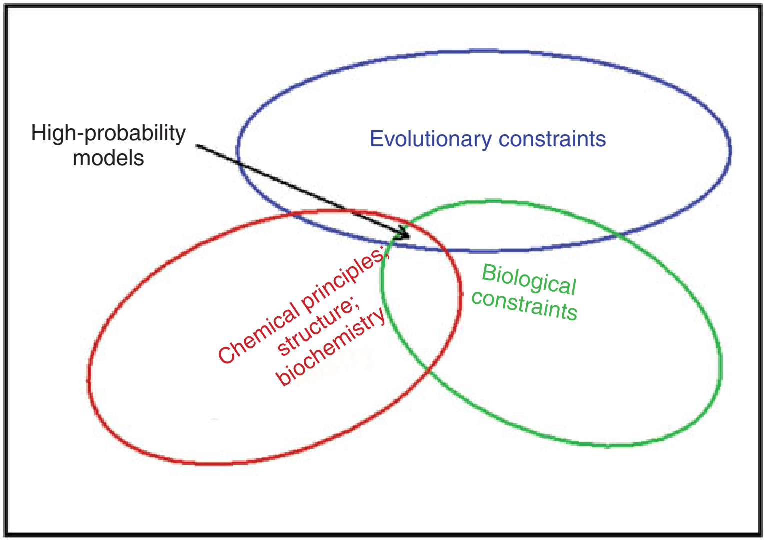

Figure 5 Venn diagram illustrating how Bayesian analysis of evolutionary constraints, in conjunction with other data sources, helps identify likely models of protein function. See discussion in text

currently is unfeasible for most forms of data, we are developing such an approach for structural data.

Finally, iteratively recycling through this entire process helps refine likely models of protein function. After an initial analysis, earlier steps may be improved, for example, by adding previous false-negative sequences to the alignment, by correcting alignment errors on the basis of detailed structural comparisons, or by defining more appropriate input sequence sets for the BPPS procedure.

5. Related methods

Other computational approaches – such as hierarchical analysis of residue conservation (Livingstone and Barton, 1993), principal component analysis (Casari *et al*., 1995), evolutionary trace (Lichtarge *et al*., 1996), positional entropy (Hannenhalli and Russell, 2000), site-specific rate shifts (Gaucher *et al*., 2002), and specificity-determining residues (Li *et al*., 2003; Mirny and Gelfand, 2002) – likewise obtain evolutionary insights into protein function based on multiply aligned sequences. CHAIN analysis complements most of these methods in that it focuses on co-conserved residues that stopped evolving long ago rather than on evolutionary changes within the context of a phylogenetic tree. It also differs in that it combines Bayesian and classical statistical inference, MCMC procedures, and molecular interaction analyses to detect – on the basis of thousands of distantly related sequences – subtle structural characteristics in atomic detail.

6. Accessibility over the Web

Because automation of these procedures is nontrivial, making CHAIN analysis programs directly available is not feasible at this time. Instead, a Web database of curated results from various analyses is being developed in collaboration with Lincoln Stein at Cold Spring Harbor Laboratory. This will facilitate experimental follow-up on CHAIN analysis predictions, primarily through mutational studies. While some mutational analyses are straightforward, we predict that other compelling hypotheses likely will require very clever experimental designs, perhaps involving unnatural amino acid substitutions (Hendrickson *et al*., 2004) or the use of drug-like molecular probes, to unambiguously confirm predicted functional roles for individual atoms.

Acknowledgments

We thank Jack Chen, Andy Reiner, and Ji-Joon Song for critical reading of the manuscript and helpful suggestions. This work was supported by NIH grant LM06747 to AFN and by NSF grants DMS0204674 and DMS0244638 to JSL.

Short Specialist Review

Large-scale, classification-driven, rule-based functional annotation of proteins

Darren A. Natale, C. R. Vinayaka and Cathy H. Wu
Georgetown University Medical Center, Washington DC, USA

1. Introduction

The high-throughput genome projects have resulted in a rapid accumulation of predicted protein sequences for a large number of organisms. Meanwhile, scientists have begun to tackle protein functions and other complex regulatory processes using global-scale data generated at various levels of biological organization, ranging from genomes and proteomes to metabolomes (metabolites synthesized by a biological system) and physiomes (the physiological dynamics of whole organisms). To fully realize the value of the data, scientists need to understand how proteins function in making up a living cell. With experimentally verified information on protein function lagging behind, bioinformatics methods are needed for reliable and large-scale functional annotation of proteins.

A general approach for functional characterization of unknown proteins is to infer function based on sequence similarity to annotated proteins in sequence databases. While this is a powerful method, numerous genome annotation errors have been detected, many of which have been propagated throughout molecular databases. There are several sources of errors (Galperin and Koonin, 1998; Koonin and Galperin, 2003). Errors often occur when identification is made on the basis of local domain similarity or similarity involving only parts of the query and target molecules. Furthermore, the similarity may be to a known domain that is tangential to the main function of the protein or to a region with compositional similarity, such as transmembrane domains. The best hit may be statistically insignificant. Errors also occur when the best hit entry is an uncharacterized or poorly annotated protein, or is itself incorrectly predicted, or simply has a different function. Aside from erroneous annotation, database entries may be underidentified, such as a "hypothetical protein" with a convincing similarity to a protein or domain of known function, or may be overidentified, such as ascribing a specific enzyme activity when a less specific one would be more appropriate.

These problems can be addressed by using a curated, hierarchical, whole-protein classification database, especially in conjunction with a rule-based system

designed specifically for large-scale annotation. Annotation rules define not only the conditions that must be met but also the fields (including function, ontology, and site-specific features) that could be confidently propagated.

2. Hierarchical whole-protein classification

2.1. The advantage of protein classification

There is an immediate advantage to using a protein classification database as a basis for annotation. This advantage is conferred by “strength in numbers”. Instead of relying on the (hopefully) accurate annotation of a single (hopefully related) protein (usually, the BLAST best hit), using curated classification databases allows reliance on the collected wisdom of multiple proteins, or at least the assurance that the members are truly related. (For the sake of this discussion, it is assumed that the query protein has been accurately assigned to a protein family of interest. This, typically, is done via specialized BLAST search, (e.g., the COG database, Tatusov *et al*., 2003), HMMer search (e.g., Pfam, Bateman *et al*., 2004), or combination of both (e.g., PIRSF, Wu *et al*., 2004). *Streptococcus agalactiae* protein gbs1797 (UniProt accession Q8E3G2) provides a good example of the usefulness of protein families for annotation. It is likely that the simple “Hypothetical protein” annotation attached to this protein is derived from the fact that its best hit has the same annotation. However, long before this protein was submitted to the sequence databases, the COG database had its predicted family annotated as “Galactose-1-phosphate uridylyltransferase” (COG1085). Similarly, *Mannheimia succiniciproducens* “Hypothetical protein MS0372” (UniProt accession Q65VN1) is predicted to be a member of PIRSF family PIRSF000378 (“Glycyl radical cofactor protein YfiD”), PFAM family PF01228 (“Glycine radical”), and InterPro family IPR001150 (“Formate C-acetyltransferase glycine radical”), all of which were available at the time of submission. Thus, several of the problems associated with propagating meaningful annotation to new proteins, including misannotated or statistically insignificant best hits, are averted by the use of protein classification databases.

2.2. Whole proteins

Are whole proteins equal to the sum of their parts? Mostly, yes. However, this is not always the case, at least for annotation purposes. For example, PIRSF000142 contains “glycerol-3-phosphate dehydrogenase (anaerobic), subunit C” proteins. The annotation of such proteins, if one were to rely on predominantly domain-centric databases alone, would likely be “Cysteine-rich iron-sulfur binding protein” (based on hits to PF02754, “Cysteine-rich domain” and PF00037, “4Fe-4S binding domain”). Worse yet are the possibilities that a protein is composed of multiple domains, but only one is described (thereby causing an underannotation by means

of omission), or the converse, where a protein is composed of only one domain but hits proteins of much longer length and likely different function (*see* Article 87, **The PIR SuperFamily (PIRSF) classification system**, Volume 6). The use of a whole-protein classification database, such as PIRSF, combined with an insistence that predicted members of a given family exhibit (near) end-to-end similarity, obviates such problems. Other predominantly whole-protein classification databases (which may or may not also contain domain families) include COGs, TIGRFAMs (Haft *et al*., 2003), PANTHER (Mi *et al*., 2005), and HAMAP (Gattiker *et al*., 2003).

2.3. Hierarchies

The annotation power of protein classification databases is rendered even more powerful if a single database contains families with progressively greater levels of similarity (i.e., hierarchies), or if different databases (with different levels) are searched. Such databases, most notably PIRSF and the database-integrating InterPro (Mulder *et al*., 2005), allow annotation at an appropriate level of specificity. Theoretically, one query protein could be confidently predicted to be a member of a parent family, but not a child family, while a different query might be confidently assigned to both levels. In such cases, the most-specific possible annotation could be propagated. For example, PIRSF001370, a large family that contains acetolactate synthase-like thiamine diphosphate-dependent enzymes, can be further divided into seven subfamilies. Two *Pseudomonas putida* members of this family (UniProt accessions Q88DY8 and Q88 N22) are annotated as the large subunit of acetolactate synthase (the latter as putative). However, only Q88DY8 belongs to subfamily PIRSF500108, which contains verified acetolactate synthase large subunits. Q88 N22 can only be confidently assigned to the parent family. Pending confirmation of activity, "thiamine diphosphate-dependent enzyme" would be a safer annotation. As these examples demonstrate, the use of a hierarchical database helps prevent over- or underannotation (*see* Article 87, **The PIR SuperFamily (PIRSF) classification system**, Volume 6).

2.4. The PIRSF system

The PIRSF protein classification system combines all of the approaches described above (Wu *et al*., 2004). The system provides protein classification from superfamily to subfamily levels in a network structure based on evolutionary relationships of whole proteins. Such classification allows identification of probable function for uncharacterized sequences. PIRSF classification, which considers both full-length similarity and domain architecture, discriminates between single- and multidomain proteins where functional differences are associated with the presence or absence of one or more domains. Furthermore, classification based on whole proteins, rather than on the component domains, allows annotation of both generic biochemical and specific biological functions.

In this system, unassigned proteins are tested against a set of hidden Markov models (HMMs) representing curated full-length protein families at different hierarchical levels. The following criteria, used by PIRSF Scan (**http://pir.georgetown.edu/pirsf**), must be met:

1. The query protein must be recognized by an HMM with a score that falls above the minimum threshold score appropriate for that family. The threshold is based on the minimum score exhibited by current curated members of the family.
2. The length of the query protein must fall within the range exhibited by true members of the family. Both the score and length thresholds are adjusted on the basis of characteristics of the protein family – that is, by taking into account standard deviations – to enable the scan program to capture divergent members for further testing.
3. The set of BLAST hits for the query must be assigned predominantly to the same PIRSF as predicted by HMM. Here, the "majority rule" principle is used, meaning that the query must hit at least 10 or one-third of the members of the PIRSF.

Fine-tuning of the match parameters is an ongoing process. Exact parameters used are described in the help document linked at the URL given above.

3. Rule-based automated annotation

Curated, hierarchical, whole-protein classification databases are, by design, well suited to large-scale protein annotation. First, the classification of whole proteins – not parts – enables specific biological function to be accurately propagated rather than only generic biochemical function (or worse, inaccurate biological function). Second, a hierarchical system of classification allows the propagation of generic biochemical function when a protein cannot confidently be assigned to a subfamily with known specific biological function. However, it is still possible to further refine large-scale automatic annotation systems. Such refinement is afforded by using annotation rules.

3.1. Annotation rules defined

An annotation rule is a set of condition/action statements. The conditions can range from the sequence-based, such as "member of family X", "contains domain Y", or "motif Z present", to the organism-based, such as "member of taxonomic lineage A" or "encodes metabolic function B". The action, typically, is the propagation of appropriate information to the query protein, but it can also include the flagging of preexisting annotation as inappropriate. Rules are most useful (and accurate) when associated with a particular family or set of families. For example, a rule written to propagate the name "Pyruvate (flavodoxin) dehydrogenase" to proteins that match its active site motif could end up wrongly propagating that term to Midasin or other

inappropriate proteins. However, if this same rule were applied only to members of the appropriate family (e.g., PIRSF000159), then only suitable proteins would be so annotated, assuming they match the motif.

Annotation rules have thus far been developed by the three members of the UniProt Consortium – the Protein Information Resource (PIR), the Swiss Institute of Bioinformatics (SIB), and the European Bioinformatics Institute (EBI). PIR has developed manually curated Site Rules (PIRSRs) and Name Rules (PIRNRs), each of which (described in detail below) is based on curated protein families of the PIRSF system. SIB has developed curated rules based on the curated HAMAP family system (Gattiker *et al*., 2003). EBI has multiple systems – the manually curated RuleBase system (Biswas *et al*., 2002) and the automatically generated Spearmint (Kretschmann *et al*., 2001) and Xanthippe (Wieser *et al*., 2004) rules. Each of these rule sets are integrated into the annotation pipeline for proteins in the UniProt Knowledgebase (Bairoch *et al*., 2005).

3.2. Advantages of rule-based propagation of functional annotation

Annotation rules add significant advantages when used in conjunction with protein classification systems for the automated propagation of information from a family to an individual protein:

- *Increased specificity*: For example, both archaea and eukarya contain homologs to the DNA polymerase sliding clamp (PIRSF002090), commonly called Proliferating Cell Nuclear Antigen (PCNA). However, though the designation PCNA is perfectly reasonable for eukarya, it is not for archaea. Furthermore, the archaeal and the eukaryal versions are not easily separable based on sequence. Therefore, the only recourse for proper naming would be a taxonomy-based rule. Another example is provided by PIRSF000532, a protein family composed of members with the same general function but different specificities. The proteins are phosphofructokinases that are either ATP dependent, pyrophosphate-dependent, or of unknown dependency. The specificity is encoded in a very small number of residues (Bapteste *et al*., 2003). Multiple instances of convergent evolution render the division of this family into subfamilies based on whole-protein similarity to be difficult if not impossible. However, rules can test for the known amino acid combinations conferring ATP or pyrophosphate dependence, thereby allowing the propagation of "ATP-dependent phosphofructokinase" or "Pyrophosphate-dependent phosphofructokinase" as appropriate. In addition, a fallback rule can be formulated such that entries failing both of the specific rules could be named the less-specific, but still accurate, "Phosphofructokinase".
- *Maintenance*: This attribute works on two levels. First, maintaining a single rule for multiple proteins is easier than maintaining those proteins individually. Second, at least as applied in UniProt, the annotation of proteins that fit a particular rule can be periodically updated to reflect changes in the rule actions. The reapplication of rule actions means that entries previously annotated on the basis of a particular rule would immediately be fitted with the new information from the updated rule.

- *More annotation fields*: The ease of maintenance fosters an increase in the number of functional annotation fields that can be "touched" by automated means. Most current methods for applying automatic annotation to individual proteins focuses specifically on the protein name (even though, in principle, other fields can be annotated as well; in practice, this is not done). However, rules afford an easy mechanism for more accurate propagation of other important annotation fields, such as position-specific sequence features, Enzyme Commission (EC) name and number, keywords, references, and Gene Ontology (GO) terms. Function-based classifications, such as EC and GO, provide useful complements to sequence-based classifications enabling, for example, studies on analogous enzymes (Galperin *et al*., 1998).
- *Standardization*: The uniform application of a rule to proteins in a given family, by definition, will create a uniformity in annotation (when warranted). When applied to protein names, such annotation becomes another controlled vocabulary, thereby significantly aiding text-based searches.
- *Evidence attribution*: Rules can themselves be annotated with information that describes the source for the rule and whether the propagatible information is based on experimental evidence or computational prediction. Storing rules with unique identifiers allows information propagated by a rule to be tagged with the rule identifier. This, in effect, forms the basis for evidence attribution describing data source, types of evidence, and methods for annotation. Such evidence attribution provides an effective means to avoid misinterpretation of annotation information and propagation of annotation errors.
- *Validation*: A large amount of inaccurate information can be (and has been) propagated to proteins using nonstringent criteria. These erroneous data are difficult to find, so nearly impossible to eradicate completely. However, annotation rules – used to propagate reliable information – can also be used to flag unreliable information through "caution" statements. Each of the annotation rule systems indicated above has this component; however, the Xanthippe system performs this function exclusively.

3.3. Annotation rules at PIR

The PIRSF classification serves as the basis for a rule-based approach that provides standardized and rich automatic functional annotation. In particular, annotation can be reliably propagated from sequences containing experimentally determined properties to closely related homologous sequences based on curated PIRSF families. PIR rules are manually defined and curated for several annotation fields, as described below. Two types of annotation rules have been developed. PIR Site Rules focus on sequence-specific features (UniProt "FT" lines). Originally designed to capture and propagate protein name (UniProt "DE" line) information, PIR Name Rules have expanded in scope to include synonyms and acronyms, Enzyme Commission (EC) name and number, Gene Ontology terms, and comment fields such as Function, Pathway, and Caution.

3.4. PIRSR Site Rules

To assure correct functional assignments, protein identifications must be based on both global (whole protein) and local (domain and motif) sequence similarities. Position-specific Site Rules enable the annotation of active site residues, binding site residues, modified residues, or other functionally important amino acid residues. To exploit known structure information, Site Rules are defined starting with PIRSF families that contain at least one known 3D structure with experimentally verified site information. The active site information on proteins is taken from the PDB (Bourne *et al*., 2004) SITE records, the LIGPLOT of interactions available in PDBSum database (Laskowski, 2001), and published scientific literature. The dataset of catalytic residues (Bartlett *et al*., 2002) is used as an authoritative source for catalytic residues in enzyme active sites.

Site rule curation involves manually editing multiple sequence alignments of representative protein family members (including the template PDB entry), building hidden Markov models (HMMs) from the conserved regions containing the functional site residues, and visualizing sequences and structures. The rules are defined using appropriate syntax and controlled vocabulary for site description and evidence attribution. The profile HMM thus built allows one to map functionally important residues from the template structure to other members of the PIRSF family that do not have a solved structure. To avoid false positives, site features are only propagated automatically if all site residues match perfectly in the conserved region by aligning both the template and target sequences to the profile HMM using HmmAlign (Eddy *et al*., 1995). Potential functional sites missing one or more residues or containing conservative substitions are only annotated after expert review with evidence attribution. Table 1 shows six example Site Rules, three for PIRSF000077 and three for PIRSF000097.

Automatic annotation generated by the PIR Site Rules will be attributed with the rule ID, which links to the rule report containing additional information. For Site Rules, the rule report will include multiple sequence alignments with highlighted site residues (Figure 1).

3.5. PIRNR Name Rules

To capture the full annotation capability of PIRSFs, PIR Name Rules (PIRNRs) were developed. As with Site Rules, each Name Rule is defined with conditions for propagation (Table 1). While most Name Rules assign protein names to all family members, many families require more specialized rules with additional conditions to propagate appropriate names and avoid overidentification or underidentification. In addition to the PCNA example of taxonomically restricted names (or activities), PIR Name Rules provide the means to account for functional variations within one PIRSF, including instances in which a protein lacks the active site residue(s) necessary for enzymatic activity, and cases in which evolutionarily related proteins

Table 1 PIR Site Rules and Name Rules for automated annotation of functional sites and standardized protein names

Rule type/ID	Condition	Propagatible annotation	Evidence
Site rule/ PIRSR000077-1	PIRSF000077 member and HMM site match	Feature: Active site	Template: UniProt:P00274; PDB:2TRX
		Residues: Cys 33, Cys 36	Status: Validated [PMID:2181145]
Site rule/ PIRSR000077-2	PIRSF000077 member and HMM site match	Feature: Site	Template: UniProt:P00274; PDB:2TRX
		Residues: Gly 34, Pro 35	Status: Validated [PMID:9099998]

		Misnomer: chorismate mutase	

have known differences in biochemical activities (such as the phosphofructokinases of PIRSF000532) or domain organization.

PIRNRs are part of a two-tier system. The first tier is the "zero-level" rule. Such rules are designed without the ability for discrimination. That is, the information propagated by such a rule will apply to all members of the PIRSF to which the rule belongs (each PIRNR will apply only to members of its cognate PIRSF, and

Figure 1 Multiple sequence alignment of PIRSF family thioredoxin (PIRSF000077), the two active site cysteines (site rule PIRSR000077-1) are boxed in red. Thioredoxins are small redox proteins that catalyze dithiol-disulfide exchange reactions. The source organisms, with the UniProt accession numbers in parentheses, are *Escherichia coli* (P00274), *Buchnera aphidicola* (P57653), *Porphyra purpurea* (P51225), *Chromatium vinosum* (P09857), *Staphylococcus aureus* (Q9ZEH4), *Lactococcus lactis* (Q9CF37), *Bacillus subtilis* (P14949), *Clostridium acetobutylicum* (Q97EM7), *Clostridium acetobutylicum* (Q97IU3), *Helicobacter pylori* (P56430), *Pseudomonas aeruginosa* (Q9X2T1), *Bacillus halodurans* (Q9K8A8), *Vibrio cholerae* (Q9KV51), *Haemophilus influenzae* (P43785), *Yersinia pestis* (Q8ZAD9), *Listeria monocytogenes* (Q9S386), and *Clostridium pasteurianum* (Q7M0Y9)

to no other PIRSF members). This ensures that every classified protein will get some annotation (assuming any information is known for the PIRSF members, and such information is deemed applicable to all members). The "higher-order" rules will fit only those members that pass additional tests. The additional tests may include taxonomic placement, presence or absence of critical domains, fit to a PIR Site Rule, or presence on manually curated inclusion (false negative) or exclusion (false-positive) lists. By definition, higher-order rules are more specific than zero-level rules. Therefore, the propagation system is designed to prevent propagation based on the zero rule when a higher-order rule applies.

Creating a PIRNR, which seeks to capture known or predicted information about a PIRSF, follows the completed curation of each PIRSF:

1. Compile known (literature) or predicted (sequence analysis) information about members of the PIRSF of interest.
2. Indicate match conditions (higher-order rules only), including
   (a) taxonomic range to which the rule should apply;
   (b) essential domains (in the form of matches to PFAM);
   (c) essential residues (in the form of matches to PIR Site Rules);
   (d) false-negatives (list known entries that should get the indicated annotation, but would otherwise fail the rule tests).
3. Indicate exclusion conditions (higher-order rules only), including
   (a) taxonomic range that should NOT get propagation;

   (b) domains that should NOT be present;
   (c) residues that should NOT be present;
   (d) false-positives (list known entries that pass all the rule tests, but should NOT get propagated information).
4. Indicate propagatible information, including
   (a) protein name (DE line) and acronym that adheres to UniProt standards;
   (b) alternative names or synonyms used in the literature, with acronyms;
   (c) comments on function, pathway, or cautions about nomenclature (as in the PIRNR025624-1 example; Table 1);
   (d) EC number;
   (e) GO terms. Only the leaf-most term is propagated.
5. Outline the scope of the rule, or provide reasons why a particular protein name was chosen as standard for the group.

4. Conclusions

Critical to our understanding of biology is accurate and up-to-date information. The process of evolution affords us the ability to make inferences about the nature of the proteins that govern biological processes, since like proteins often perform like (if not exact) functions. Unfortunately, this same process has been far from a smooth transition from state to state. The result is that inferences made about one protein based on similarity to another protein using automated methods are often suspect. This is more than a mere annoyance. The lack of rigorous methods for propagating appropriate information hampers knowledge discovery by either reducing the associations that can be made, or by producing associations that should not be made. However, the recent development of methods for better annotation hold much promise for preventing – and even reversing – the previous trend toward rampant misinformation. The combination of hierarchical, whole-protein classifications and rule-based large-scale annotation pipelines is a significant step in the right direction.

Signal peptides and protein localization prediction

Henrik Nielsen
Center for Biological Sequence Analysis, The Technical University of Denmark, Lyngby, Denmark

1. Introduction

In 1999, the Nobel prize in Physiology or Medicine was awarded to Günther Blobel "for the discovery that proteins have intrinsic signals that govern their transport and localization in the cell". Since the subcellular localization of a protein is an important clue to its function, the characterization and prediction of these intrinsic signals – the "zip codes" of proteins – has become a major task in bioinformatics.

Here, I will review the most important methods for the prediction of subcellular localization, also known as protein sorting. Owing to the limited space, this review is far from complete; especially, applications that are not publicly available on-line are ignored. Generally, there are two approaches to protein localization prediction: signal detection, that is, prediction of the sorting signals themselves, and prediction based on global properties (amino acid composition and/or physicochemical variables) that are characteristic of different subcellular compartments.

2. Secretory signal peptides

The best known "zip code" is the secretory signal peptide, which targets a protein for translocation across the plasma membrane in prokaryotes and across the endoplasmic reticulum (ER) membrane in eukaryotes (von Heijne, 1990). It is an N-terminal peptide, typically 15–30 amino acids long, which is cleaved off during translocation of the protein across the membrane. There is no simple consensus sequence for signal peptides, but they typically show three distinct compositional zones: an N-terminal region that often contains positively charged residues, a hydrophobic region of at least six residues, and a C-terminal region of polar uncharged residues with some conservation at the −3 and −1 positions relative to the cleavage site.

In a very early bioinformatics application, von Heijne (1986) developed a weight matrix for recognition of the signal peptide cleavage site. This weight matrix has found an extremely wide usage. It does not exist as a WWW-server, but it is included in PSORT (see below).

A newer method is SignalP (**http://www.cbs.dtu.dk/services/SignalP**), which is based on neural networks (NNs) and hidden Markov models (HMMs) (Bendtsen *et al*., 2004). See Article 98, **Hidden Markov models and neural networks**, Volume 8 for an introduction to these machine-learning methods. A comparison of signal peptide prediction methods showed that both NNs and HMMs outperform the weight matrix (Menne *et al*., 2000). This still seems to be the case, even though a newer application using weight matrices has become available (Hiller *et al*., 2004) (**http://www.predisi.de/**).

The HMM included in SignalP is a complex architecture that does not adhere to the well-known profile HMMs. However, Zhang and Wood (2003) showed that the task can be done with an only slightly lower performance using a profile HMM implemented in the standard HMMER package (the model can be downloaded from **http://share.gene.com/**).

It should be noted that far from all proteins with secretory signal peptides are actually secreted to the outside of the cell. In gram-negative bacteria, they by default end up in the periplasmic compartment, and a separate mechanism is needed to secrete them to the growth medium (Pugsley *et al*., 1997). In eukaryotes, proteins translocated across the ER membrane are by default transported through the golgi apparatus and exported by secretory vesicles, but some proteins have specific retention signals that hold them back in the ER, the golgi or the lysosomes. In general, these retention signals are poorly characterized, one exception being the ER retention signal that has the consensus sequence KDEL or HDEL (van Vliet *et al*., 2003).

Some transmembrane proteins also have a cleavable secretory signal peptide that initiates translocation, whereafter the translocation is halted by a transmembrane α-helix that acts as a stop-transfer signal, leaving the protein integrated in the membrane. For a comparison of various publicly available methods for predicting transmembrane helices, see Chen *et al*. (2002) (*see* Article 38, **Transmembrane topology prediction**, Volume 7 and Article 65, **Analysis and prediction of membrane protein structure**, Volume 7).

Transmembrane helices often lead to false-positives in signal peptide prediction and vice versa. Recently, a combined HMM that deals with this problem by modeling both these signals, Phobius, (**http://phobius.cgb.ki.se**) has become available (Käll *et al*., 2004).

Other membrane proteins do not have transmembrane domains, but are linked to the membrane by a covalently attached lipid group. Prokaryotic lipoproteins have signal peptides that are cleaved by a special signal peptidase, and their cleavage site has a characteristic consensus signal with a 100% conserved cysteine in position +1. Two publicly available signal peptide prediction methods are designed to recognize prokaryotic lipoprotein signal peptides: LipoP, (**http://www.cbs.dtu.dk/services/LipoP/**), which is based on a combination of NNs and HMMs (Juncker *et al*., 2003); and SPEPlip, (**http://gpcr.biocomp.unibo.it/predictors/**), which is based on NNs combined with a simple pattern matching (Fariselli *et al*., 2003). In eukaryotes, some proteins are linked to the membrane by a glycosylphosphatidylinositol (GPI) anchor at the C-terminus or a myristoyl anchor at the N-terminus. These can be predicted with the big-Π and NMT tools (**http://mendel.imp.univie.ac.at/mendeljsp/sat/index.jsp**) (Eisenhaber *et al*.,

2003), and the myristoylation also with Myristoylator (**http://www.expasy.org/tools/myristoylator/**) (Bologna *et al*., 2004).

3. Other localization signals

The target peptides of chloroplasts and mitochondria are also N-terminal cleavable peptides (Schatz and Dobberstein, 1996). They are less well characterized than the secretory signal peptide, but they are both rare in negatively charged residues and able to form amphiphilic α-helices (Bannai *et al*., 2002; Bruce, 2000).

A widely used method to predict mitochondrial transit peptides (mTPs) is Mitoprot (**http://websvr.mips.biochem.mpg.de/cgi-bin/proj/medgen/mitofilter**) (Claros and Vincens, 1996). It is a feature-based method, using a linear combination of a number of sequence characteristics such as amino acid abundance, maximum hydrophobicity, and maximum hydrophobic moment (α-helix amphiphilicity) that are combined into an overall score.

A newer method, MITOPRED (**http://mitopred.sdsc.edu**), does not rely on mitochondrial targeting signals, but is based on Pfam domain occurrence patterns and the amino acid compositional differences between mitochondrial and non-mitochondrial proteins (Guda *et al*., 2004).

For chloroplast transit peptides, there is a NN-based method available, ChloroP (**http://www.cbs.dtu.dk/services/ChloroP/**) (Emanuelsson *et al*., 1999). A successor of ChloroP is TargetP (**http://www.cbs.dtu.dk/services/TargetP/**), which provides prediction of both chloroplast transit peptides, mitochondrial transit peptides, and secretory signal peptides (Emanuelsson *et al*., 2000). Both ChloroP and TargetP use a combination of NNs to calculate a transit or signal peptide score, and a weight matrix to locate the transit peptide cleavage sites.

Another NN-based method is Predotar (**http://genoplante-info.infobiogen.fr/predotar/**) (Small *et al*., 2004). In contrast to TargetP that uses moving windows to calculate the transit peptide score, Predotar uses a fixed window comprising the first 40–60 amino acids of the sorting signal. Like TargetP, it predicts mitochondrial, chloroplast, and secretory signals.

Bannai *et al*. (2002) tested a large number of physicochemical features of N-terminal parts of proteins with signal or transit peptides and obtained a combination of simple rules that yielded a discriminative performance fairly close to that of TargetP. Interestingly, a simple hydrophobicity scale even outperformed the NN-based TargetP on plant signal peptides. The resulting method is called iPSORT (**http://hypothesiscreator.net/iPSORT/**).

Not all localization signals are N-terminal and cleavable. Nuclear localization signals can occur internally in the sequence and are not cleaved. The method PredictNLS (**http://cubic.bioc.columbia.edu/predictNLS/**) (Cokol *et al*., 2000) predicts nuclear localization by comparing the query sequence to a database of experimentally verified NLS sequences and derived signals.

Peroxisomes also have their own protein import machinery. Two uncleaved signals are known: the C-terminal PTS1 and the N-terminal PTS2. PTS1 with the consensus sequence -SKL is best known, and a predictor is available (**http://mendel.imp.univie.ac.at/PTS1/**) (Neuberger *et al*., 2003).

4. Global property methods

In addition to the recognition of the sorting signals, prediction of protein sorting can exploit the fact that proteins of different subcellular compartments differ in global properties, reflected in the amino acid composition. Andrade *et al*. (1998) found that the signal in the total amino acid composition, which makes it possible to identify the subcellular location, is due almost entirely to surface residues. While the signal-prediction methods are probably closer to mimicking the information processing in the cell, methods based on global properties can work also for genomic or EST sequences where the N-terminus of the protein has not been correctly predicted. One drawback is that such methods will not be able to distinguish between very closely related proteins or isoforms that differ in the presence or absence of a sorting signal.

The NNPSL method (**http://predict.sanger.ac.uk/nnpsl/**) (Reinhardt and Hubbard, 1998) uses NNs trained on overall amino acid composition to predict localization. The method distinguishes between three bacterial compartments (cytoplasmic, periplasmic, and extracellular) and four eukaryotic compartments (cytoplasmic, extracellular, mitochondrial, and nuclear). Interestingly, plant proteins were found to be very poorly predicted, and are not included in the present method.

Nair and Rost (2003), also working with NNs, found that prediction could be improved by using information from protein structure. Specifically, they calculated amino acid composition separately for three categories of secondary structure (helix, sheet, and coil) and for surface-accessible residues. Naturally, the improvement was most pronounced when applied to proteins of known structure, but even a predicted secondary structure (according to an NN) was able to enhance prediction. The resulting method is implemented in a database, LOC3D (**http://cubic.bioc.columbia.edu/db/LOC3d/**), and a web server, LOCtarget (**http://cubic.bioc.columbia.edu/services/LOCtarget/**) (Nair and Rost, 2004).

There is a rapidly growing number of subcellular localization prediction methods based on amino acid composition and related features. The SubLoc method (**http://www.bioinfo.tsinghua.edu.cn/SubLoc/**) (Hua and Sun, 2001) is based on support vector machines (SVMs, *see* Article 110, **Support vector machine software**, Volume 8). The data set used to train SubLoc is that of Reinhardt and Hubbard (1998), but the predictive performance is significantly better than the NN. Three newer SVM applications are Esub8, PLOC, and ESLpred. Esub8 (**http://bioinfo.tsinghua.edu.cn/CoupleLoc/eu8.html**) (Cui *et al*., 2004) uses the amino acid composition of the first and last half of each sequence and distinguishes between eight subcellular locations. PLOC (**http://www.genome.ad.jp/SIT/ploc.html**) (Park and Kanehisa, 2003) uses, in addition to amino acid composition, amino acid pairs (adjacent or separated by one to three positions) to enhance prediction. It distinguishes between as many as twelve subcellular locations. ESLpred (**http://www.imtech.res.in/raghava/eslpred/**) (Bhasin and Raghava, 2004) is a four-location predictor based on the NNPSL data, which uses both amino acid composition, adjacent amino acid pairs, PSI-BLAST output, and physicochemical properties.

It should be stressed that no prediction method is better than the data set used to train it. One problem that is rarely properly addressed in global property methods is homology in the data. If the data used to test a method has sequences

that are significantly homologous to sequences in the training data, the apparent performance of the method is an overestimate. To compute a true generalizable performance, the data set should be reduced so that no homologous pairs remain (Hobohm *et al*., 1992). Reinhardt and Hubbard (1998) reduced their data set, but only removed sequences with more than 90% identity, which is clearly much higher than the homology threshold. Newer methods, with the exception of PLOC, are trained with the Reinhardt and Hubbard (1998) data or without homology reduction at all. Therefore, care should be taken when comparing performance measures.

5. Integrated methods

PSORT (**http://psort.nibb.ac.jp** or **http://www.psort.org/**) (Nakai and Kanehisa, 1991, 1992; Nakai and Horton, 1999) is an integrated system of several prediction methods, using both sorting signals and global properties. Some of the components are developed within the PSORT group, others are implementations of methods published elsewhere, including selected PROSITE patterns. PSORT is the only publicly available system that shows this degree of integration. In addition to localization (up to 16 different possible locations in plant cells), it also predicts motifs for posttranslational modifications such as lipid attachment.

All the constituent predictors provide feature values, which are then integrated to produce a final prediction. In the original version, PSORT I, the integration was done in the style of a conventional knowledge base using a collection of "if-then" rules, while the newer PSORT II version uses quantitative machine-learning techniques, such as probabilistic decision trees and the k nearest neighbors classifier to integrate scores from all the features. PSORT II is available for animal and yeast proteins (11 locations), while plant proteins still have to rely on PSORT I.

For gram-negative bacteria, there is a recently improved version named PSORT-B (**http://www.psort.org/psortb/index.html**) (Gardy *et al*., 2003) discriminating between five possible locations (cytoplasm, inner membrane, periplasm, outer membrane, and extracellular). It uses a combination of homology searches to proteins of known localization, PROSITE motifs, signal peptide, and transmembrane helix predictors based on HMMs, and a SVM-based predictor using amino acid composition.

Drawid and Gerstein (2000) developed a different integrated system for localizing all the proteins in the yeast genome to one of the five possible compartments (cytoplasm, nucleus, mitochondria, membrane, or secretory pathway). It is a Bayesian system integrating 30 features comprising both specific motifs (e.g., signal sequences or the HDEL motif), overall properties of a sequence (e.g., surface composition or isoelectric point), and whole-genome data (e.g., absolute mRNA expression levels or their fluctuations). The method is not available for submission of new sequences, but predictions for all known yeast genes can be retrieved (**http://bioinfo.mbb.yale.edu/genome/localize/**).

Transmembrane topology prediction

Lukas Käll and Erik Sonnhammer
Center for Genomics and Bioinformatics, Karolinska Institutet, Stockholm, Sweden

1. Introduction

Transmembrane (TM) proteins make up about 20% of all protein sequences known, yet less than 1% of all the known structures. This discrepancy is due to the fact that TM proteins are hard to overexpress and crystallize, and therefore difficult to examine with X-ray diffraction or NMR. It is, however, much easier to determine the *TM topology*. By this, one normally means localizing all TM segments as well as determining which subcellular compartment the loops in between the TM segments are exposed to. The problem can be addressed either experimentally using antibodies or fusing the examined gene with reporter genes or, as will be discussed here, by using a TM topology predictor.

TM topology predictors normally assume that all cellular membranes can be treated equally, regardless of which organelle or cell type they surround. The location of a loop can be classed as being on the originating side, meaning the side of a membrane from which the TM protein was inserted (normally the cytoplasm), or the translocated side, the opposite side of the membrane. The commonly used "inside" and "outside" notation is confusing and should be avoided. For instance, the inside of an organelle is the translocated side, which is normally considered the "outside."

2. TM prediction principles

Early TM helix prediction methods were based on theoretically or experimentally determined hydropathy indices of hydrophobic properties for each amino acid. For the examined protein, a hydropathy plot was calculated by summing the hydropathy indices over a window of a fixed length. A heuristically determined cutoff value was then used to indicate possible TM segments, see for instance (Argos *et al*., 1982; Kyte and Doolittle, 1982). An important improvement to this strategy came from the observation that positively charged amino acids (arginine and lysine) are overrepresented on the originating side loops of TM proteins (von Heijne and Gavel,

1988). This gives a hint about the location of the loops and led to the development of the first automated full TM topology prediction methods, for example, TOPPred (von Heijne, 1992). This method first scans the sequence for certain putative TM segments and then selects the putative segments that maximize the difference in charged amino acids in loops, summed over each side separately. Instead of only using a hydropathy index, some methods use a combination of this and the indices for amino acids known to be frequent near the end of membrane helix ends, for example, SOSUI (Hirokawa *et al*., 1998). Other methods are letting a sequence profile, for example DAS (Cserzo *et al*., 1997), or an Artificial Neural Network, for example PHDhtm (Rost *et al*., 1996), detect potential TM segments.

Instead of first scanning the sequence for TM segments and then sorting out the topology as a second step, the search for TM segments can be integrated with the evaluation of possible topologies in one step. The amino acid distribution of the investigated sequence is compared to precalculated expected amino acid distributions in each type of topologically distinct region (TM helices, originating side loops, and translocated side loops) of a TM protein (see Figure 1). Given correlation measurements between the amino acid distributions of the examined protein and the expected amino acid distributions in different topological regions, the most likely topology can be predicted. A nice feature of this approach is the ability to model all parts of the protein so that all topogenic signals are properly weighted, which is preferable to giving priority to the hydrophobic signal. This was first done by a dynamic programming algorithm in the method Memsat (Jones *et al*., 1994). Pure probabilistic approaches to the problem have been taken as well. A commonly used probabilistic framework for such tasks is the hidden Markov model (HMM). Some popular HMM-based predictors are TMHMM (Sonnhammer *et al*., 1998; Krogh *et al*., 2001) and HMMTOP (Tusnady and Simon, 1998).

A common problem for the methods mentioned above is that they have a tendency to falsely classify signal peptides as TM segments. This is a natural consequence of the fact that signal peptides, as well as TM segments, contain a long hydrophobic region (*see* Article 37, **Signal peptides and protein localization**

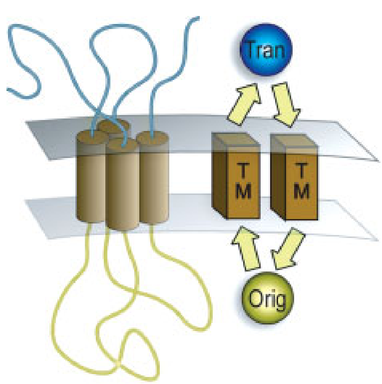

Figure 1 Modern TM predictors compare the amino acid distributions of a query protein (left) with the different regions (TM segments, originating side loops and translocated side loops) of a cyclic model (right) trained on known TM proteins

prediction, Volume 7). To discriminate between the two types of sequence features, a recently published method, Phobius (Käll *et al*., 2004), employs a combined HMM model of both signal peptide and TM structure.

β-barrel TM proteins seem to be hard to predict with the classical TM prediction methods since their TM segments are generally shorter and have a different amino acid composition than the α-helical TM segments. Lately, some methods to predict such structures have been published (Martelli *et al*., 2002; Zhai and Saier, 2002).

A common way to improve the performance of a predictor is not only to look at the examined sequence but instead to first find homologs using alignment tools such as Blast (Altschul *et al*., 1990) and then predicting the topology of the whole alignment. The idea is that topology should be conserved in a family, and by looking at the entire family there is less chance of mispredicting single, atypical members. Examples of such methods are TMAP (Persson and Argos, 1997) and PHDhtm (Rost *et al*., 1996).

A good practice when predicting TM topology is to compare the results from several different predictors. This is most easily done by running a Meta server, that is, a server that runs a number of different prediction programs. The results may be delivered in the form of e-mails from the different underlying predictors, like for Meta-PP (Eyrich and Rost, 2003), or they may be displayed side by side graphically, as by Sfinx (Sonnhammer and Wootton, 2001) (see Figure 2). The results from multiple methods may also be combined by a consensus predictor. Such a predictor only contains a weight for each method and heuristics for combining the results. An example is ConPred II (Xia *et al*., 2004).

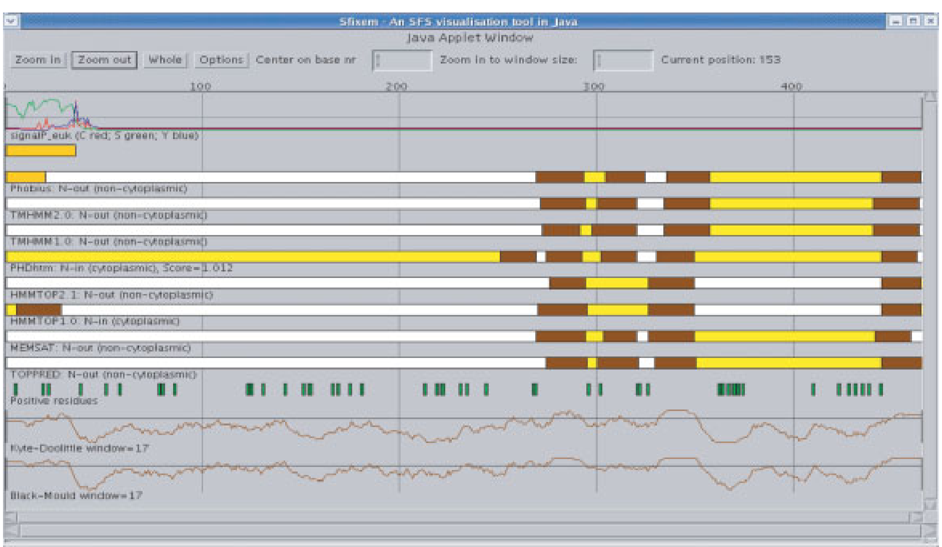

Figure 2 A screen shot from the Sfinx workbench analyzing the sequence GAC1_RAT (Swissprot: P23574) with multiple prediction methods. TM topology predictions are shown as colored boxes, and the used method is indicated underneath. Brown color indicates a TM segment, white a loop on the translocated side, yellow a loop on the originating side, and orange a signal peptide. Using a Meta server like this shows that different predictors often produce different results. The consensus topology is easily found

3. Common problems

There are a number of sequence features that are problematic for most TM topology predictors. As mentioned before, signal peptides are known to easily get mixed up with TM segments. Some TM prediction methods, therefore, require the user to remove potential signal peptides by the usage of a signal peptide predictor such as SignalP (Bendtsen *et al*., 2004). This is, however, not trivial because signal peptide predictors are known to often falsely predict TM segments as signal peptides.

In TM proteins containing many TM helices, a few of the helices may be shielded from the membrane by the other TM helices. Such shielded helices are usually less hydrophobic than normal TM helices and are therefore easily missed by some TM topology predictors.

Some TM proteins contain α-helical regions that are buried in the membrane but do not cross the membrane. Such regions are often present in voltage-gated ion channels. Most predictors predict those regions as TM segments, and therefore get their topology wrong. Likewise, long hydrophobic α-helical regions buried within globular domains of soluble proteins can easily be mistaken as TM segments.

4. Benchmarking

To be able to compare different TM prediction methods, one normally assembles a test set with known topologies and examines how well each prediction agrees with it. For such benchmark experiments, it is important to collect adequate test sets since a biased test set could easily favor some of the predictors. Over the years, a couple of such test sets have been assembled, for example, the MPtopo (Jayasinghe *et al*., 2001), Möller (Möller *et al*., 2000), and TMPDB (Ikeda *et al*., 2003) sets.

Table 2 The number of correctly predicted topologies according to different benchmarking studies. Values marked with asterisk (*) were measured on older versions of the method

Method	Möller *et al*.	Ikeda *et al*.	Chen *et al*. High resolution	Chen *et al*. Low resolution
TMHMM 2.0	47%	48.4%	45%*	85%*
HMMTOP 2.1	45%*	54.1%	61%	79%
PHDhtm - single	18%	–	54%	68%
PHDhtm - multiple	–	–	66%	67%
Memsat 1.5	41%	45.1%	–	–
Number of proteins	188	122	36	165

Most modern TM topology predictors are based on machine-learning algorithms, that is, they use training sequences to assemble general knowledge about the sequence features of TM proteins. When comparing the performance of different methods, it is therefore essential to not include the training data of any of the compared methods in the test. This is, however, problematic, because so few TM topologies are known that when removing all the training set proteins, only a few proteins with dubious topologies are left. In addition, benchmarking sets generally seem to be easier to predict than genomic data (Käll and Sonnhammer, 2002).

It, therefore, may not be so surprising that different benchmark studies come to different conclusions about which TM topology prediction method is better. Möller and colleagues (Möller *et al*., 2001; Möller *et al*., 2002) rate TMHMM as the best method, while Ikeda and colleagues (Ikeda *et al*., 2002) rate HMMTOP as the best. Chen and colleagues (Chen *et al*., 2002) use two different test sets, one containing topologies with known 3D structures (high resolution) and one containing topologies without known 3D structure (low resolution). PHDhtm scored best on the high-resolution set, while TMHMM scored best against the low-resolution set. Table 2 lists a few different assessments of accuracy by a number of prediction methods. As the reader can see, the reported performance differs significantly. Hence, the reported performance figures for TM prediction methods should be interpreted with caution, both in terms of absolute and relative accuracy.

IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis

Yuri I. Wolf
National Institutes of Health, Bethesda, MD, USA

1. Introduction: philosophy of profile-based analysis

Sequence evolution is a largely stochastic process. Random undirected mutations occur during the DNA replication. Depending on the effect of these mutations on the structure and function of the protein, they may become fixed in the population. According to a neutral theory of molecular evolution (Kimura, 1983), the majority of the fixed mutations are effectively neutral. As two proteins diverge, following either speciation or gene duplication within the same genome, they accumulate substitutions and their similarity gradually declines over time. Random, mostly neutral, character of protein evolution ensures practical impossibility of sequence convergence of unrelated proteins.

Given a reasonable mathematical model of amino acid composition and molecular evolution of proteins, one can obtain precise quantitative estimates of several important measures. In particular, the distribution of sequence similarity measures (fraction of identical amino acids or alignment score) for random (i.e., unrelated) sequences can be computed (Karlin and Altschul, 1990). If a pair of sequence produces an alignment, whose similarity exceeds random expectations, it is a strong indication of the homology of the proteins. However, if the proteins diverged long ago, their similarity drops to the level where it is undistinguishable from the statistical "noise". For such proteins, one cannot justify the claim of homology on the basis of their alignment score. The level of similarity where confident inference of homology becomes impossible is often referred to as "twilight zone" (Doolittle, 1981).

Evolution of proteins is characterized by remarkable nonuniformity of mutability across sequence sites. Some parts of the polypeptide chain are extremely tolerant to amino acid substitutions, while others require specific residues to preserve the function and/or structure of the protein (Doolittle, 1981). The overall nonuniform shape of the distribution of evolution rates between sites can be taken into account in the sequence evolution models, but there is no general way to account for properties of particular sites in particular protein families.

```

Figure 1 (a) A fragment of an alignment of two distantly related homologous sequences (tufB and coaA). (b) A fragment of an alignment of two unrelated sequences (tufB and fimI). Asterisks indicate residues identical between the two sequences

Two pairwise alignments with the same (low) level of sequence similarity are equivalent from a statistical point of view; however, they might have very different biological meaning, readily distinguishable by an expert in the particular group of proteins. Both alignment fragments in Figure 1 have 14–16% of identical residues. The relevance of alignment A is self-evident to anyone familiar with P-loop ATPases (Saraste *et al*., 1990), as it correctly juxtaposes important residues of the so called Walker A motif; alignment B is a spurious match of unrelated proteins.

The distinction comes easy if the proteins are well studied and the relative importance of different fragments and residues of the polypeptide chain is known. For less-characterized proteins, this approach is, by definition, unproductive.

The difference in mutability of different protein sites is easy to observe comparing multiple proteins separated by various evolutionary distances. Sites, evolving at slower rates, are more often seen as amino acid matches in pairwise comparisons; fast-evolving sites do not display conservation beyond the random expectation. Compiling a multiple alignment of distant but unambiguously related proteins allows one to assess relative prominence of different sites. Taking into account multiple alignments built for two proteins that display low sequence identity could help answer the question about the relevance of the similarity: if the alignment of these sequences, however poor, largely follows sites, conserved in each of the multiple alignments, then the alignment is likely to be biologically significant (Figure 2a); if the two multiple alignments are discordant, the juxtaposition is probably spurious (Figure 2b). Going from closely related proteins to more and more distant ones, one can learn features specific for a given level of evolutionary relationships and extend the range of confident biological conclusions far into the “twilight zone” (Doolittle, 1981).

It is possible to formalize this observation introducing the notion of sequence profile (Gribskov *et al*., 1987). Each position in a profile corresponds to a site in a protein; but, unlike a straightforward protein sequence, each site is represented not by a single amino acid but rather by a spectrum of possible variants. Highly variable sites are represented by a widely dispersed distribution of amino acids; for conserved sites, the distribution is sharply biased toward a particular amino acid (or class of amino acids, e.g., “aromatic” or “positively charged”). The simplest form of a profile representing an alignment of length L is a matrix of $L \times 20$ dimension where each column corresponds to a site in alignment, each row corresponds to an amino acid, and each matrix element shows a frequency of a given amino acid in a given alignment position. In practice, instead of straightforward frequencies,

Figure 2 (a) Alignment of sequences in Figure 1(a) juxtaposed with multiple alignments for tufB and coaA. (b) Alignment of sequences in Figure 1(b) juxtaposed with multiple alignments for tufB and fimI. Asterisks indicate the same pairs of residues as in Figure 1. Alignments are colored according to physicochemical properties of amino acid residues

profiles often contain precomputed weights, associated with occurrence of a given amino acid in a given position of the alignment; such profile is often referred to as position-specific score matrix (PSSM). PSI-BLAST (Altschul *et al*., 1997) and HMMer (Durbin *et al*., 1998) program families are among the most widely used profile-based sequence analysis software.

2. PSI-BLAST: Position-specific Iterated BLAST

Position-specific iterated BLAST was developed at the National Center for Biotechnology Information (NCBI) (Altschul *et al*., 1997). Its profile-based features dramatically improved sensitivity and specificity of protein sequence similarity search.

PSI-BLAST generalizes the regular BLAST scoring scheme for a comparison between a query PSSM and a single target sequence. Query PSSM is computed from the query-anchored multiple alignment (sometimes referred to as "master-slave alignment" with the query in the role of the master sequence). Scores in each column of the PSSM reflect the frequencies of different amino acids in the corresponding alignment position "diluted" by background amino acid frequencies to dampen the effect of sampling error. Query-target alignment is scored using the PSSM instead of a presupplied scoring matrix, as it is done in regular BLAST. To alleviate the effect of many highly similar sequences "outvoting" less abundant divergent forms, the amino acid frequencies used to compute the PSSM are adjusted according to a sequence weighting scheme by Henikoff and Henikoff (1994).

The primary mode of PSI-BLAST application is the iterative search starting with a single sequence as the query. The first iteration consists of a regular BLAST search against a given database. Sequences, found to be confidently similar with the query (i.e., with e-values below a specified threshold), contribute to a query-anchored multiple alignment. Weighted amino acid frequencies and position-specific scores are computed for each alignment position. Well-conserved sites, naturally, tend to favor a particular amino acid (or a narrow range of amino acids), producing position-specific scores that severely discriminate between "right" and "wrong" amino acids. Amino acid frequencies in highly variable sites approach background frequency distribution, resulting in scores uniformly close to zero. In the subsequent iterations, target sequences are compared against the query PSSM. Matches or mismatches against sites conserved in the previous iteration are scored in a sharply contrasted manner; variable sites are scored neutrally regardless of the target amino acid. Thus, target sequences that preserve the pattern of conserved sites are scored higher than those that have the same number of matching sites, but spaced in different manner. In each iteration, the signal contained in the conserved sites is reinforced by new matches; the noise in variable sites is further diluted. Highly diverged homologous sequences that were scored low in previous iterations usually get progressively higher scores, rising in the ranked list of hits.

Obviously, the success of PSI-BLAST search strongly depends on the database content and on the query choice. If the database contains a great number of sequences, related to the query, with gradually declining similarity, there is a good chance that the iterated procedure will eventually retrieve them all. It is especially helpful if the selected query is equidistant from the other homologs and does not contain too many insertions and deletions compared to the majority of its relatives. If there is a wide gap between the immediate relatives of the query and its more distant homologs, the search is likely to prematurely converge after a few iterations (i.e., no new sequences can be recognized as significantly similar because the narrow group of the closest relatives does not allow for sufficient discrimination between important and irrelevant sites). Another problem with PSI-BLAST search is the potential of "PSSM explosion". If an unrelated sequence somehow makes it into profile (usually because of its compositional bias), it is possible that it influences the scores strong enough that at the next iteration its own relatives would also be scored high. Subsequent iteration would bring more hits, unrelated to the original query. It often leads to a widespread "flattening" of

the profile, with loss of distinction between the conserved and variable sites, further reducing the search specificity.

The PSSM, constructed in the course of the iterated search, can be saved and later reused, provided that the query and the search parameters, affecting statistical calculations, remain the same. If this search is performed against the same database, it has simply the effect of bypassing the previous (often time-consuming) iterations. The PSSM, however, can be used to search a different database. Typically, one constructs family-specific profiles by iterative searches against a sequence database, containing maximum available diversity of sequences. These profiles are later used for searches in particular genomes or other specialized datasets. Protein PSSM queries can be also used in a search against a nucleotide sequence database, the latter being dynamically translated in all six frames.

PSI-BLAST can initiate a search with a PSSM constructed from a multiple sequence alignment. One of the alignment sequences (with gap characters removed) must be designated as the master query; thus many different, although similar, PSSMs can be obtained from the same multiple alignment. This approach has an advantage of the possibility to use a high-quality expert-curated alignment to make a profile.

Recent modifications of PSI-BLAST introduce further modification of the scoring matrices depending on the amino acid frequency bias in the query (composition-based statistics). Practically, this feature greatly increases the search specificity for the price of a certain reduction of sensitivity; this option is especially attractive for fully automated projects.

PSI-BLAST is distributed as a stand-alone program that can be used for a search against a local database. Web-based PSI-BLAST service, provided by the National Center for Biotechnology Information, contains an important additional feature: a possibility of direct user control over the sequences, contributing to the PSSM construction. Checking and unchecking control boxes, the user can include or exclude sequences regardless of their formally computed statistical significance. Allowing an expert opinion to influence the PSSM composition gives the approach much greater flexibility.

3. IMPALA: Integrating Matrix Profiles and Local Alignments

Accumulation of a collection of high-quality profiles poses a technical challenge of reversing a profile search scenario. Instead of using PSSM queries in a search against a sequence database, it is often practical to run a (series of) single-sequence query against a library of profiles. IMPALA, released in 1999, provided this capability (Schaffer *et al*., 1999). A collection of PSI-BLAST profiles and corresponding master query sequences needs to be processed into a searchable library for use with IMPALA. Unlike BLAST family of programs, which use empirical “X-dropoff” algorithm to produce and score local alignment between the query and the target (Altschul *et al*., 1997), IMPALA implements rigorous Smith–Waterman algorithm (Smith and Waterman, 1981), producing provably optimal results. This, of course, trades off the execution speed for the accuracy. Additionally, IMPALA included several advanced techniques of PSSM handling

(notably, finer scaling of the scores), later incorporated into mainstream BLAST software. IMPALA is distributed as a stand-alone suite of programs.

4. RPS-BLAST: Reverse PSI-BLAST

RPS-BLAST (Marchler-Bauer *et al*., 2002) is a direct implementation of BLAST search algorithms in a reversed manner – with a protein sequence query and a PSSM library as a target. Like with IMPALA, PSI-BLAST profiles are postprocessed into a searchable database for use with RPS-BLAST. RPS-BLAST has a significant advantage in running speed over IMPALA, with only a minor degradation of sensitivity. RPS-BLAST is the search engine of the CD-search service (Marchler-Bauer *et al*., 2002) of the National Center for Biotechnology Information, available through a Web interface.

Introductory Review

The domains of life and their evolutionary implications

Carl R. Woese

University of Illinois at Urbana-Champaign, Urbana, IL, USA

1. Introduction

Over a century ago, Darwin wrote: "The time will come I believe, though I shall not live to see it, when we shall have very fairly true genealogical trees of each great kingdom of nature" (Burkhardt and Smith, 1990). From his phrasing, it is clear that Darwin had more in mind than just the Plant and Animal Kingdoms. Indeed, by Darwin's time bacteria ("infusoria" as they were then called) were not only recognized but also recognized as evolutionarily distinct from both plants and animals. Yet, twentieth century biology did not seem particularly interested in Darwin's vision of an all-embracing phylogeny. Biology was now headed in an entirely new (reductionist) direction, one in which evolution was far from a central concern. The classical evolutionists of the twentieth century, Darwin's descendants, were seriously interested only in animals and plants. And the microbiologists, who should have been vitally interested in bacterial phylogenies, became discouraged over the difficulty of determining a phylogenetic classification for bacteria (on the basis of classical criteria), and threw in the towel – just as the problem was about to yield (Woese, 1994; Stanier and van Niel, 1962). Before doing so, however, they invented a guesswork solution to the question of bacterial relationships, the "prokaryote" (Stanier and van Niel, 1962). All bacteria were arbitrarily declared to be of a kind; all were "prokaryotes", which meant that (1) all shared a common general type of "prokaryotic" organization and (2) all had come from common "prokaryotic" ancestral stock (Stanier and van Niel, 1962; Stanier *et al*., 1963). Although no facts supported it, the guesswork "prokaryote" rapidly became doctrine, thereby allowing microbiologists to wash their hands of the vexing problem of bacterial genealogies. To this day, Biology remains saddled with the "prokaryote", although the concept has long ago been exposed for what it is – pure rhetoric (Woese, 2004).

However, Darwin's vision of a comprehensive genealogy, one that embraced all life, did not permanently fade. Unknowingly, molecular technology came to the rescue (Sanger and Tuppy, 1951; Sanger and Thompson, 1953). While their gross properties – shapes, physiologies, motilities – reveal little about bacterial genealogies, their genealogies are just as apparent as any others on the molecular

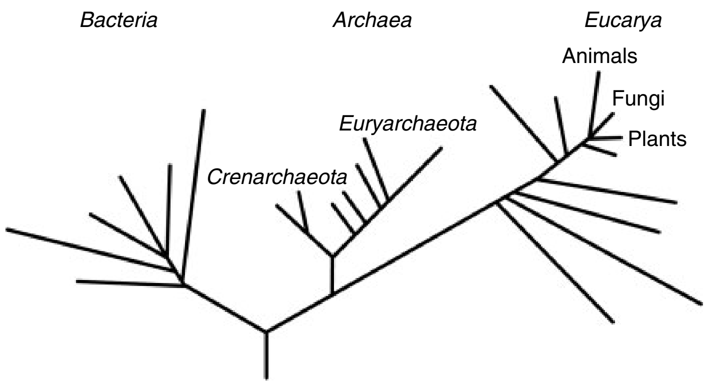

Figure 1 The universal phylogenetic as determined by ribosomal RNA sequences analyses (Reproduced from Woese CR (2002) by permission of National Academy of Sciences, U.S.A.)

level. Once this was recognized (which took a while), techniques for sequencing macromolecules (the first of which were developed in the 1950s) provided more than enough information to establish all genealogical relationships. By the early 1970s, a program to determine bacterial genealogies through a molecular sequencing was underway (Fox *et al*., 1980). The result was nothing short of spectacular; see Figure 1. For the first time, all the "great kingdoms of nature" were brought together in a common evolutionary framework. Evolutionary study had burst the bounds of the Animal and Plant Kingdoms.

2. The primary lineages

As Figure 1 demonstrates, life on this planet divides in the first instance into three primary lineages, now known as the Bacteria (or eubacteria), the Archaea (which, like Bacteria, comprises single-celled organisms), and the Eukarya (or eukaryotes) (Woese *et al*., 1990). As the tree structure also indicates, the distinctions (phylogenetic distances) among them is a striking one, far greater than are any seen within the individual primary groupings themselves. However, this strictly quantitative linear measure cannot capture the distinction's full quality. Each of the three primary lineages is associated with a unique type of cellular organization. It has long been obvious that this is true of the eukaryotic cell (the classical textbook picture of a cell), but it is only recently that it has also been recognized for the organization of the archaeal cell (Graham *et al*., 2000). The tripartite division of life is easily seen in various of the cell's subsystems. The information processing systems – translation, transcription, and genome replication – exhibit this most strongly.

Consider translation. Most of the mechanism's componentry is universal, but the bacterial version easily distinguishes itself from the other two in two ways: (1) in terms of novel (unique) componentry and (2) in terms of the degree of sequence dissimilarity among components that are universal in distribution (Olsen and Woese, 1996). With regard to novel componentry, the bacterial ribosome contains a relatively small number ribosomal proteins (∼5 in the small subunit ribosome; ∼15

in the large) not found in the ribosomes of either the archaea or eukaryotes. On the other hand, the archaeal ribosome shows a (somewhat larger) number of ribosomal proteins (~12 and ~20, small and large subunits respectively) not found in the bacteria, *all* of which (save one) *are* found in the eukaryotic ribosome! (The eukaryotic ribosome in its turn has a small number of additional ribosomal proteins that the others lack.) With regard to universal componentry, the bacterial ribosomal protein sequences are, in almost all cases, readily distinguishable from their archaeal and eukaryotic counterparts (Olsen and Woese, 1996; Vishwanath *et al*., 2004). The difference is great enough to have a qualitative aspect to it, a difference in "genre". The eukaryotic versions of the universal ribosomal proteins are almost exclusively of the archaeal genre.

From the evolutionist's perspective, the most intriguing aspect of the translation componentry is the tRNA charging enzymes, the so-called aminoacyl-tRNA synthetases (aaRSs) (Woese *et al*., 2000). Unlike others of the ribosomal componentry, these enzymes have obviously been subject to extensive horizontal gene transfer (HGT). But the pattern characteristic of the ribosomal proteins is, nevertheless, evident here too: for the majority of the 20-odd aaRS types, there exists a bacterial and an archaeal genre (the latter found in most of their eukaryotic counterparts as well). What is seen among the aaRSs but not with the ribosomal proteins, however, are cases where the archaeal genre of a given aaRSs shows up in one or a few bacterial taxa – an obvious result of HGT. The "generic" distinction between the bacterial and the archaeal/eukaryotic versions of the aaRSs (and by extension all of the ribosomal componentry) has not been caused by, but has persisted in spite of, extensive horizontal mixing of genes among the three primary lineages (Woese *et al*., 2000). This generic distinction stands witness to some unknown ancient evolutionary transition.

The evolutionarily pattern seen in the case of translation reappears in transcription, but in a somewhat more blatant form. The generic difference between bacteria and the other two domains is most extreme in the genome replicating apparatus. In the case of transcription, the three principal subunits of the bacterial DNA-dependent RNA polymerase have counterparts in the other two domains, but a pronounced difference in "genre" again distinguishes the bacterial from the archaeal (and related eukaryotic) sequences thereof (Langer *et al*., 1995; Olsen and Woese, 1996). Moreover, the archaeal version of the transcription polymerase contains additional subunits (~6) not found in the bacteria, and these (as now might be expected) have homologs in the eukaryotic RNA polymerases. Continuing the similarity with translation, the eukaryotic versions of the transcription apparatus contain still further subunits unique to themselves (Langer *et al*., 1995). The transcription initiation complex used by Bacteria is simply different from those found in the Archaea and Eukarya, with the archaeal version again looking like a simpler form of the eukaryotic (Bell and Jackson, 2001).

What all this means is uncertain at present. I do not feel one should jump to the simplistic conclusion that the archaeal/eukaryotic similarity implies specific relationship between the two at the organismal level. It is best to hold the matter open, leaving us with a stimulating question.

A different impression emerges when relationships among the three organismal domains are viewed from the perspective of cellular metabolism (Rogozin *et al*.,

2003). Here, much of eukaryotic intermediary metabolism seems to have been derived from the bacteria. Some of the eukaryotic intermediary metabolism, of course, was acquired from the endosymbiont that evolved into the mitochondrion: and the corresponding genes readily trace back to an ancestry within the alpha proteobacterial phylum (the taxon from which the original mitochondrial endosymbiont came). Yet, the bulk of the eukaryote's acquired metabolic capacity traces phylogenetically to a region deep on the stem of the bacterial lineage (Canback *et al*., 2002), significantly below the earliest bifurcations known for the recognized bacterial lineages. In other words, the type of "bacteria" that might have given rise to the bacterial-type metabolism found in eukaryotes today predated what we take to be the most recent common ancestor of all extant bacterial lineages; which asks the question of what kinds of organisms these ancient "proto-ancestral eubacteria" were.

All this raises the interesting question as to why eukaryotic metabolism does not reflect archaeal metabolism, as one sees with the archaeal information processing systems. The answer may be that the archaea have little to offer in the way of metabolic versatility, at least of a kind that has been indigenously generated. The euryarchaeota, for example, exhibit five general classes of phenotype: the methane producers; the anaerobic thermophilic sulfate reducers (Archaeglobales); the haloarchaea (heterotrophs that grow aerobically in high salt environments); the Thermoplasmales (a collection of heterotrophs growing at elevated temperatures and low pH); and the Thermococcales (again, a rather nondescript high-temperature heterotrophic phenotype) (Olsen *et al*., 1984). The native euryarchaeal phenotype is clearly methanogenesis, for it is phylogenetically spread throughout the group, in four separate phyla. The other four euryarchaeal phenotypes, however, are each confined to a particular (major) lineage within the overall group, all but one of them, the Thermococcales, being sister groups to one of the methanogenic lineages (the Methanomicrobiales). The interesting thing about these non-methanogenic phenotypes is that the evolution of their diverse metabolisms is the result of acquiring key genes from the eubacteria (Baliga *et al*., 2004; Deppenmeier *et al*., 2002). It would appear that only the eubacterial lineage has been metabolically inventive, and that the other two domains, archaea and eukarya, have fashioned the bulk of their metabolic diversity by importing bacterial genes.

3. Probing the depths of evolutionary time

Molecular sequence-based analyses take us into virgin territory, early evolutionary stages that could not even begin to be conceptualized by the classical biologist. Sequence comparisons provide evidence of evolutionary events, possibly predating cells as we know them – evidence we have yet to fully understand (Woese, 2002; Woese, 2004). For example, many protein families (formed through duplication and functional diversification of some ancestral gene) had to have arisen before the stage represented by the "root" of the universal tree. The protein couple EF-Tu and EF-G are an example. The two play complementary roles in translation and both are essential to the process – being found in all organisms. Yet, the two have clearly evolved from the same common ancestral protein (gene) (Olsen and Woese,

1996). (Evidence also suggests that neither of them has been subject to significant HGT.) In detecting their relatedness, one is sensing evolution at stages prior to the "most recent common ancestor" of extant life. A similar conclusion can be adduced for others of the cellular systems, for example, certain multisubunit enzymes of universal distribution in which two or more of the subunits come from the same family; or certain universal metabolic pathways in which enzymes at different steps in the pathway contain subunits whose sequences have familial relationship; and so on. All of this is raising the important question of what the "root" of the universal organismal tree actually represents (Woese, 2002; Woese, 2004). Traces of some mysterious "Wonder Land" of primitive evolution lie hidden in the sequences (and structures) of extant molecules.

4. Gene shuffling

The strange phenomena being unearthed by genomic probings into the depths of evolution are raising serious questions about our simplistic picture of evolution, which served so well when we had only to explain the evolutionary ebb and flow for "modern cells" and organisms (particularly the plants and animals). Unfortunately, when reported, new and revolutionary findings often come wrapped in hyperbole, so that a disinterested appreciation of the facts usually requires deconstructing the exaggerated interpretations that accompany them. Fortunately, there exists a touchstone of evolutionary common sense, and that, as always, remains Darwin. It is nothing short of incredible that words written well over a century ago (in "Origin of Species") are directly relevant and essential to our conceptualization of evolution today (Darwin).

The phenomenon that most confounds molecular evolutionists is HGT. Although HGT has been known for several decades, it is only with the accumulation of large amounts of genomic sequence information that its full evolutionary impact has been appreciated. It seems that, given sufficient time, HGT can affect the majority of (if not all) genes in the genome (Doolittle, 1999a; Gogarten *et al*., 2002; Bapteste *et al*., 2004). Not only does HGT provide a major source of evolutionary novelty, it can also result in the subtle replacement of a cellular function by some alien equivalent. This latter consequence of HGT becomes increasingly problematic as phylogenetic inference is extended further into the past (to the deep branches in the universal tree). The question, of course, is *how* problematic this type of HGT becomes in the limit; can it actually erase the entire organismal genealogical record, which would mean that we are deceiving ourselves in trying to infer universal phylogenetic trees? There are many who think this the case, and have proposed alternative evolutionary scenario to account for the genomic sequence data (Doolittle, 1999a; Gogarten *et al*., 2002; Bapteste *et al*., 2004; Doolittle, 2000; Doolittle, 1999b). It is common to read about "rerooting", "uprooting", or outright "felling" the universal organismal tree (Doolittle, 2000). Chief among the alternative interpretations is the "Web of Life" (see Figure 1; Bapteste *et al*., 2004; Sapp, 1994), which not only casts doubt on the validity of the current Tree of Life but also questions the scientific value of representing evolutionary descent as a tree.

This confusion is only apparent. It disappears with a dose of Darwinian insight. "Descent with variation" is a central Darwinian tenet. It is important to note that Darwin did not specify the nature of variation, other than viewing it as occurring in small steps, that is, any given variation is only a minor perturbation on the existing organismal design. It was the twentieth century neo-Darwinian geneticists who defined variation, establishing unequivocally that it can be brought about by point mutations and the like. They made one mistake, however, which has carried through to this day (and underlies the present confusion); and that was to assume that localized mutations are the *only* source of variation. Now we know they are not: variation is also the product of horizontal acquisition of genes (an idea long ago entertained, historians tell us (Bateson, 1913; Sapp, 1994), by the great English geneticist William Bateson and others). In other words, HGT is perfectly consistent with Darwin's original view of variation – and that is how we should view it.

Although adaptation to new environments often involves HGT (among eubacteria or archaea), there have been no documented cases of horizontal gene acquisition changing the basic nature of the organism. HGT drastic enough to do that is something that has only been *postulated*. HGT and outright cellular fusion events are central to almost all speculation concerning the origin of the eukaryotic cell (Doolittle, 1998; Hartman, 1984; Martin and Muller, 1998). The endosymbiotic origin of the mitochondrion is often cited as an example of this; but it is not. Although the endosymbiotic bacterium that ultimately evolved into the mitochondrion was indeed degenerated almost to the point of unrecognizability in the process, nothing of the sort happened to the eukaryotic cell itself; acquisition of a mitochondrion left the basic eukaryotic cellular organization intact (Kurland and Andersson, 2000).

Let us consider separately the two main types of HGT, that which introduces new functionality and that which surreptitiously replaces an endogenous function by an alien equivalent (homolog). Variation of the first type is clearly adaptive and that of the second, adaptively neutral. Darwin eschewed the use of adaptive characters in genealogical reconstruction, saying " . . . adaptive characters, though of paramount importance to the being, are of hardly any importance in classification . . . " (Darwin, 1859). Although Darwin understood that the accumulation of variations over long periods of time drastically change the character of an organism, he held that, despite this, genealogically telling (essential) characteristics persisted (at least among animals or plants) although obviously decreasing in number the further back in time the genealogy is traced. Looking at Figure 2 of Doolittle (1999b), it is apparent that the huge genetic flows suggested by the (thick) arrows for the most part represent (horizontally acquired) variations that are adaptive in nature are involved with what Darwin called "the general place of each being in the economy of nature" (Darwin, 1859). To suggest, as Figure 2 of Doolittle (1999b) does, that these horizontal flows of adaptive characters are genealogically telling is misleading.

The *history* of (organismal) descent (whose essence lies in variation) should not be confused with the genealogical *record* thereof (whose essence lies *in* variant characteristics). Strictly speaking (and practically speaking in the case of distant relationships), a genealogy is merely a record of descent, no matter how

uninformative it otherwise may be. Darwin again: " . . . we have to discover the lines of descent by the most permanent characters, however slight their vital importance may be" (Darwin, 1859). Thus, the key question here is whether there exist organismal genes (characters) that have permanently resided within the genomes of particular organismal lineages long enough to serve as reliable genealogical markers over the interval of genealogical interest – whether the interval be, for example, as short (recent) as the descent of the mammals or vertebrates in general, or as long (ancient) as that of all archaea. Darwin was under no illusion that the number of genealogically informative characters (genes, in today's terms) had to be large or that the genealogical record diminished the further back in time genealogy is traced. (That is only common sense.) Thus, the modern notion that genealogical inference must somehow be based upon the entire genome (and reflect some kind of genomic consensus) is wrong headed, especially when it is applied to the very ancient genealogical record. (Common sense alone dictates that ancient records should be scant, minimal – and they will involve only the most permanent features of the organisms, as Darwin said.) A representation of descent that lumps the overwhelming number of adaptive characters with genealogically informative ones, as indeed the reticulated "thicket" of Figure 2 in Doolittle (2000) does, completely obscures any organismal genealogical trace that may be present (especially at the "base" of the phylogenetic tree). This then gives the false impression that an ancient genealogically trace of organismal descent does not actually exist. Could this be true?

As we have seen above, there exists strong evidence that genes are capable of tracing organismal lineages at least as far back into the past as the "root" of the universal tree (Figure 1). Recall the above discussion of the (20-odd) aminoacyl-tRNA synthetases, all of which have been subject to extensive HGT, but despite this, exhibit (albeit in eroded form) the same "generic" pattern of phylogenetic relationship among the primary lines of descent that characterizes the other components of the translation apparatus (which latter have not undergone extensive, wide ranging HGT) (Olsen and Woese, 1996). This pattern (generic distinction) cannot have been caused by any HGT that occurred subsequent to the evolutionary stage represented by the "root" of the universal tree. The pattern is indeed a genetic trace of a major organismal evolutionary transition that predated the stage represented by the tree's "root". Thus, Darwin's original statement (quoted above) that ultimately we would "have very fairly true genealogical trees of each great kingdom of nature" seems remarkably prescient today.

In summary, given that rRNA is a central, integral part of the cell (and so relatively unlikely to have undergone significant HGT; Fox *et al*., 1977), there can be little doubt that the overall validity of the branching orders in the universal phylogenetic tree based upon rRNA sequence analyses does indeed approximate the true organismal genealogical tree. The sole issue that remains in doubt – and a challenging one it is – is what the "root" of this (r-RNA-based) tree represents. Is it a "root" (ancestor) in the classical sense of that word (as, for example, when biologists speak of the common ancestor of all vertebrates), or does the "root" not signify an organismal ancestor at all, but some evolutionary transition in the process of evolving cellular life – a kind of "origin of species" that Darwin in his day could have known nothing about?

5. Darwin, common descent, and the root of the universal tree

Darwin's position on the common ancestry of life is relevant here, for we credit him with declaring that all life arose from one "primordial form". Actually, Darwin did not require this to be the case; he merely entertained it as a possibility (Darwin, 1859). It was his twentieth century successors who confidently asserted it as a doctrine, "The Doctrine of Common Descent". (Darwin explicitly knew the number of ancestral "primordial forms" to be irrelevant to the Theory of Evolution, and was comfortable with both "a few forms or ... one" (Darwin, 1859).) In the twentieth century, a single ancestral form seemed the unavoidable consequence of the fact that all organisms shared a common complex core of biochemistry. No one at the time entertained the alternative that this commonality could also have been achieved through HGT. Today, "Common Descent" must be treated as an important question, but no longer a Doctrine.

The key to understanding what the "root" of the universal tree signifies is understanding what defines the (phylogenetic) span and frequency of HGT. Clearly, the function encoded by a gene is the strongest determinant. But that cannot be all, for among the most important functions in the cell, there exists a great difference in their susceptibility to horizontal gene displacement. Analyses shows that the primary defining factor here is the ways in and degree to which a given component is integrated into the cellular fabric. Look, for example, at the differences in how HGT has affected the componentry of the cellular translation mechanism. Almost all of that mechanism's central componentry is highly resistant to horizontal gene displacement *except* for the aminoacyl-tRNA synthetases (as discussed above). What distinguishes the latter componentry from the other parts of the mechanism is modularity: aminoacyl-tRNA synthetases interact with cellular componentry in general only minimally (Woese *et al*., 2000), which means that there exist relatively few constraints upon the shapes, sizes, and compositions of these enzymes. This, plus the fact that the molecules upon which these enzymes operate, the tRNAs, are universal in distribution and very uniform in shape, makes the aminoacyl-tRNA synthetases relatively susceptible to (neutral) horizontal gene displacement. In other words, it is the integration of componentry into the cellular fabric that largely determines the degree to which they are subject to horizontal gene displacement (and the character of the that displacement). From this it follows that the simpler the design of a cell, the more susceptible its componentry is to HGT. In the early stages (proteinaceous) of cellular evolution, cell design (their organization) must have been far simpler than it is in modern cells. Hence, while HGT plays a relatively minor (but still important) role in (microbial) evolution today, in earlier stages of cellular evolution, it must have been an absolutely dominant factor in their evolution.

Carrying this line of reasoning to the extreme, one can envision an early stage in the evolution of cells wherein genetic exchanges among all evolving entities were high enough that evolution of cellular organization behaved as though it were a communal rather than an individual (individual lineages) affair, which when viewed in retrospect would give the *appearance* of a unitary common ancestor, a typical "root" to a universal organismal tree (Woese, 2002). All evolving cell designs could usefully partake of the inventions created by any other evolving cell design. At this

stage, there would be no such thing as a permanent genealogical trace residing in the organismal genome; any such trace would be ephemeral only.

The root of the universal tree may then represent a transitional stage, one in which a primitive evolutionary dynamic (dominated by HGT) gives way to the modern type of evolution dynamic (having much lower levels and restricted range of HGT) – when a "pre-Darwinian" evolutionary world transforms into the familiar "Darwinian" one. It may well be that the three primary cell types, the (eu)bacteria, archaea, and eukarya, each existed in some primitive kind of form in this pre-Darwinian world. Evidence suggesting this comes from certain gene families, ones that reasonably had to have existed prior to the stage represented by the "root" of the universal tree, but that are confined to only one of the three primary cell lineages – a fact hard to explain otherwise (Woese, 2004). Since the transition from a pre-Darwinian condition to a Darwinian one would be a function of the cell design undergoing that transition, this would almost certainly mean that each of the three primary cell types underwent the transition from the pre-Darwinian evolutionary world to the Darwinian one at a different time. In other words, there were, in effect, at least three different "primordial forms" from which extant life arose.

It is clear that molecular approaches to evolution are going to show us a very different world of evolution than that early twentieth century biologists envisioned. But wonderfully, a world more in keeping with, and with the spirit of, Darwin's simple original conception, than with the twentieth century neo-Darwinian evolution that replaced it.

1. Introduction

Biology has been profoundly changed by the development of techniques to sequence DNA. The advent of rapid sequencing in conjunction with the capability to assemble sequence fragments into complete genome sequences enables researchers to read and analyze entire genomes of organisms. Parallel progress has been made in algorithms to study the evolutionary history of proteins. The techniques rely on the ability to measure the similarity of protein sequences in order to determine the likelihood that different proteins are descended from a common ancestor. It is therefore possible to reconstruct families of proteins that share a common ancestor.

Combining these two capabilities, we can now not only determine which proteins are coded within an organism's genome but we can also discover the evolutionary relationships between the proteins of multiple organisms. Phylogenetic profiling is the study of which protein types are found in which organisms.

In order to perform phylogenetic profiling, one must first establish a classification of proteins into families. An example of such a classification scheme across a broad range of fully sequenced organisms is the Clusters of Orthologous Groups (Tatusov, 1997), where an attempt is made to group together proteins that perform a similar function. Next, each organism is described in terms of which protein families are coded or not coded in its genome.

As we will see in this review, this simplified representation is useful for exploring the evolutionary history of an organism as well as for studying the function of protein families and how they may be related to observable phenotypes.

2. Genome phylogeny

Species phylogenies have traditionally been constructed by measuring the evolutionary divergence in a particular family of proteins or RNAs (Fitch, 1967). The most commonly used sequence for such phylogenetic reconstructions is that of the small subunit ribosomal RNA. The advantages of using this RNA gene are that it is found in all organisms, and it has evolved relatively slowly, thus permitting the construction of phylogenies between distant organisms.

Access to the complete genomes of organisms offers a new approach to phylogenetic reconstruction. Rather than looking at the evolution of a single protein or RNA family, it is now possible to compare the gene content of two organisms. This general approach to phylogenetic reconstruction has been applied in a variety of ways (Fitz-Gibbon, 1999; Snel, 1999; Tekaia, 1999; Lin, 2000; Montague, 2000; Wolf, 2001; Bansal, 2002; Clarke, 2002; House, 2002; Li, 2002).

Several metrics have been used to measure the similarity of two organisms on the basis of their gene contents, including the percentage of genes shared by the two species. Furthermore, phylogenetic trees may be reconstructed using several techniques including distance-based phylogenies and parsimony. In general, the trees constructed using whole genome comparisons are similar to those using small subunit rRNA sequences, with occasional discrepancies of interest (Figure 1).

3. Coevolution of protein families

Before fully sequenced genomes became available, the computational study of protein function relied entirely on the detection of sequence similarity. The general notion upon which these studies are based is that proteins with detectable sequence similarity are likely to have evolved from a common ancestor and thus by definition are homologs. Furthermore, such proteins are likely to have preserved common structure and function. Therefore, similarity detection may be used to assign a putative structure and function to proteins that have a sufficient degree of sequence similarity to an experimentally characterized protein. The definition of "sufficient degree" of similarity has been at the center of much research. Depending on the methodology used to determine sequence similarity, various statistical tests have been devised to determine whether two proteins have truly evolved from a common ancestor.

Although techniques based on sequence similarity are powerful, they are unable to inform us about a possible structure or function of a protein family that does not contain experimentally characterized members. This is a significant limitation because a large fraction of all protein families currently fall within this category. Phylogenetic profiling may be used to address this problem, and give us at least partial functional information on these protein families by determining the pathway or complex to which a protein belongs.

Unlike the application of phylogenetic profiling to genome phylogeny where we were interested in measuring the similarity of organisms based on their profile of gene families, here we wish to measure the similarity between the profiles of the families themselves. To accomplish this, we measure the co-occurrence or coabsence of pairs of protein families across genomes (see Figure 2). The underlying

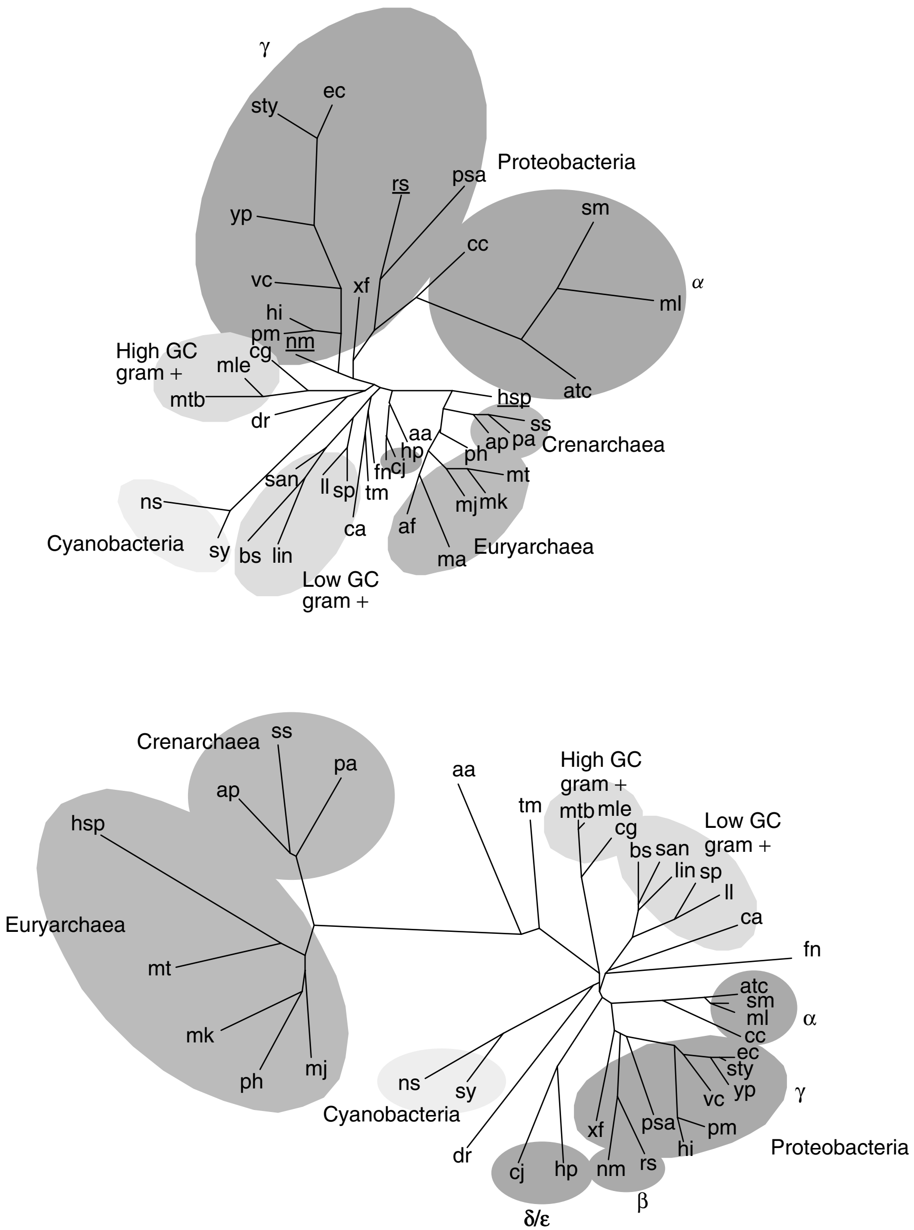

Figure 1 Phylogenetic trees of prokaryotes, based on gene content (upper tree; House, 2002), and small subunit ribosomal RNA sequence (lower tree), constructed using on-line analysis tools at the Ribosomal Database Project (**http://rdp.cme.msu.edu**) (Cole, 2003). A few notable discrepancies are shown in the gene content tree as underlined taxa

Figure 2 Clustered phylogenetic profiles of human HMBS (hydroxymethylbilane synthase), ALDH3 (aldehyde dehydrogenase), and FTHFD (formyltetrahydrofolate dehydrogenase) genes. The profiles are computed over 83 organisms shown on the top. Red indicates that a homolog of the human gene was found in the corresponding organism and black that it was not. The profiles have been clustered using hierarchical clustering (Eisen, 1998)

assumption of this method is that pairs of nonhomologous proteins that are present together in genomes, or absent together, are likely to have coevolved; that is, the organism is under evolutionary pressure to encode both or neither of the proteins within its genome and encoding just one of the proteins lowers its fitness.

It has been observed that coevolved protein families are likely to be members of the same pathway or complex (Huynen, 1998; Pellegrini, 1999). This is not surprising since it is more efficient for an organism to retain all or none of the subunits of a complex, or members of a pathway, since preserving only a fraction of these would not retain the function of the complex or pathway yet would entail their wasteful synthesis. Phylogenetic profiling has therefore emerged as a powerful method to group proteins together into cellular complexes and pathways.

Notice that protein families clustered on the basis of their phylogenetic profiles need not possess any sequence similarity. Therefore, phylogenetic profiling is able to determine functions for proteins families with no experimentally characterized members, thus going beyond the capabilities of conventional sequence similarity–based techniques.

4. Computing phylogenetic profiles

To compute phylogenetic profiles for each protein coded within a genome, one can use several approaches. One of these is to first define orthologous proteins across genomes. Orthologs are proteins that have descended from a common ancestor by way of speciation. Although the actual calculation of orthologs is not trivial, an estimate of groups of orthologous proteins has been compiled in the Clusters of Orthologous Groups (COG) database (Tatusov, 1997). Armed with these clusters, a profile may be trivially calculated by enumerating the organisms that are represented in each COG.

Another approach to establishing a phylogenetic profile is to identify homologs of a protein using a sequence alignment technique. Along these lines, a popular method is to define a homolog of a query protein to be present in a secondary genome if the alignment, using BLAST (Altschul, 1997), of the query protein

with any of the proteins encoded by the secondary genome generates a significant alignment. The result of this calculation across N genomes yields an N-dimensional phylogenetic profile of ones and zeroes for the query protein. At each position in the phylogenetic profile, the presence of a homolog in the corresponding genome is indicated with a 1 and its absence with a 0.

There is no need to restrict phylogenetic profiles to contain only entries of 1's and 0's. Various methods have been used in which the entries of the phylogenetic profile measure the similarity of two proteins. As an example, one method uses the inverse of the log of the E value from a BLAST search as the similarity metric (Date, 2003).

5. Estimating the probability of coevolution

Once the phylogenetic profiles have been computed, one needs to determine the likelihood that two proteins have coevolved on the basis of the similarity of their profiles. A variety of techniques have been reported to compute these probabilities. Here, we briefly review a few of them.

The first approach is the computation of the similarity between two phylogenetic profiles using the Hamming distance (Pellegrini, 1999). The Hamming distance is the number of bits that differ between the two profiles. Although this is a simple measure to compute, it is limited by not providing a probability estimate of observing this distance.

It is possible to obtain such an estimate of the probability that two proteins coevolve by using the hypergeometric distribution. If we assume that the two proteins A and B do not coevolve, we can compute the probability of observing a specific overlap between their two profiles by chance by using the hypergeometric distribution:

$$P(k'|n, m, N) = \frac{\binom{n}{k'}\binom{N-n}{m-k'}}{\binom{N}{m}} \tag{1}$$

where N represents the total number of genomes analyzed, n the number of homologs for protein A, m the number of homologs for protein B, and k' the number of genomes that contain homologs of both A and B (Wu, 2003). Because P represents the probability that the proteins do not coevolve, $1 - P(k > k')$ is then the probability that they do coevolve.

A similar approach attempts to compute the likelihood of coevolution using the mutual information between two phylogenetic profiles (Date, 2003; Wu, 2003):

$$MI(A, B) = H(A) + H(B) - H(A, B) \tag{2}$$

where

$$H(A) = -\sum p(a) \ln p(a) \tag{3}$$

and

$$H(A, B) = -\sum p(a, b) \ln p(a, b) \tag{4}$$

Here, the sums are over the possible states that the profiles can assume. If two profiles are identical, their mutual information is zero. Dissimilar profiles have positive mutual information scores. One advantage of the mutual information approach is that it can be applied to nonbinary phylogenetic profiles, whereas the hypergeometric function cannot.

6. Recovery of pathways and complexes

Protein pairs that coevolve are likely under some evolutionary pressure because their functions are coupled: preserving one without the other disables their combined function. This scenario may occur if the proteins are subunits of cellular complexes or components of pathways.

It is possible to test this hypothesis starting from pathway annotation. Several databases have been developed that through extensive manual curation have categorized proteins into pathways (Tatusov, 2003; Kanehisa, 2004; Camon, 2004).

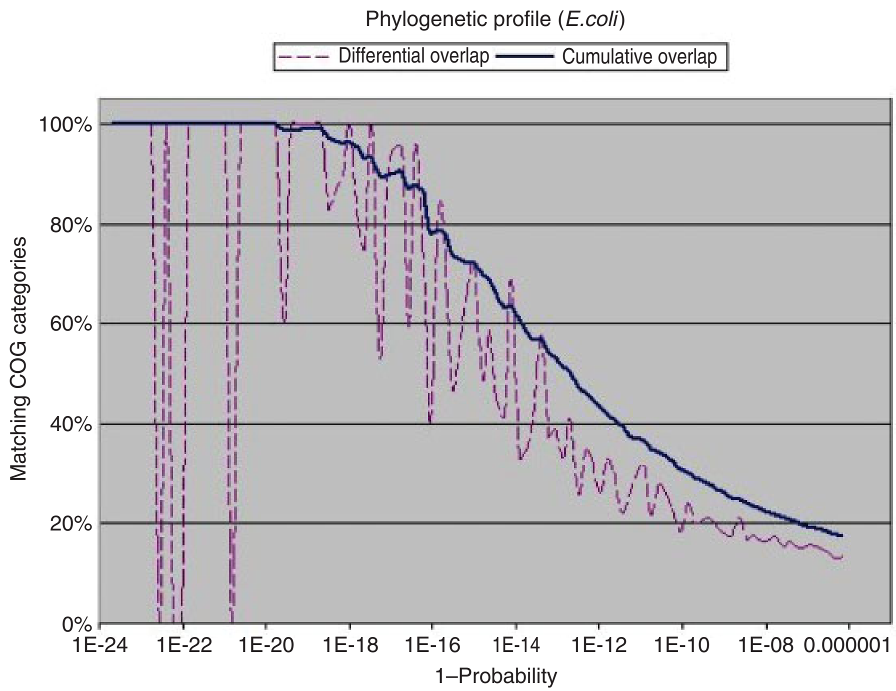

Figure 3 The probability that two genes have coevolved as a function of their likelihood to belong to the same pathway. The probability is computed using the hypergeometric function (see text). The pathways are obtained from the COG databases (Tatusov, 2003). Pairs of genes with significant *P*-values (on left) are nearly always found to belong to the same pathway

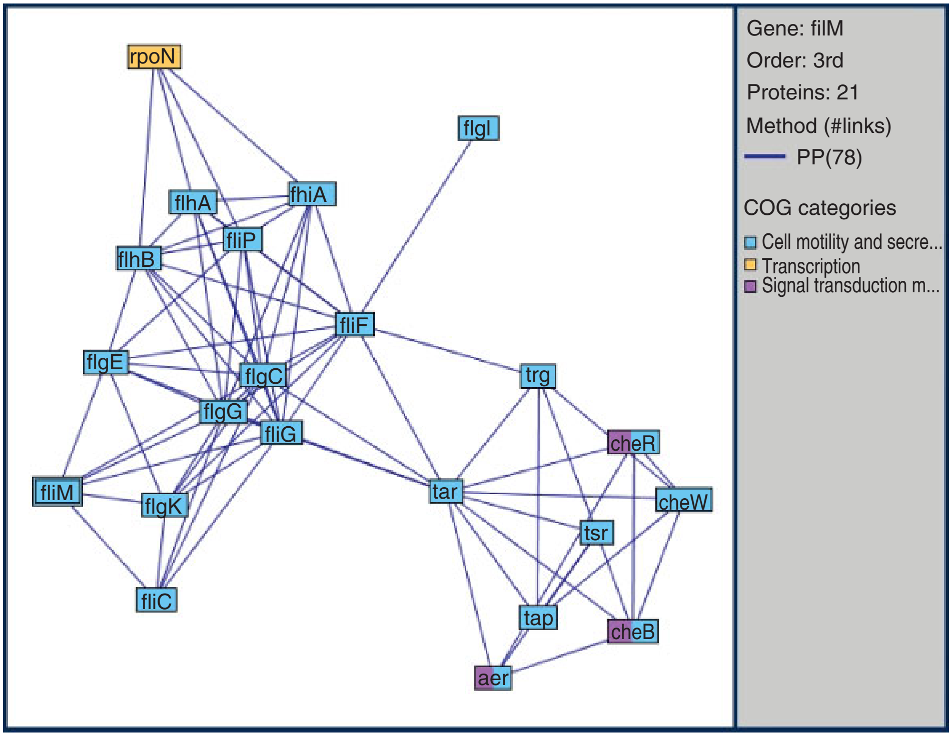

Figure 4 Clusters of *Escherichia coli* proteins that are predicted to coevolve by the phylogenetic profile analysis and that form a large network. The network shows a cluster of proteins (flg and flh genes) that are components of the bacterial flagella. A second cluster includes components of the chemotaxis pathway (che genes). These two clusters are linked to each other, indicating that flagellar and chemotaxis clusters have coevolved in bacteria

In Figure 3, we show that proteins that are likely to have coevolved (have significant *P*-values) are likely to belong to the same pathway (using the COG pathway definitions, Tatusov, 2003). In fact, we find that protein pairs with significant *P*-values nearly always belong to the same pathway. A similar curve could also be constructed using protein complexes instead of pathways, yielding similar results (Bowers, 2004).

By combining all pairs of coevolving proteins with significant *P*-values, we can generate a vast network. This is because if protein A is found to coevolve with B, and is thus said to be functionally linked to B, B may then be linked to C, C to D, and so forth. By examining clustered groups of proteins within this network, one can identify the protein components of pathways and complexes (Strong, 2003; Von Mering, 2003). An example of such a network is shown in Figure 4. Here, we see that many of the components of the flagella form a cluster, as do the components of the chemotaxis pathway. Furthermore, the network also illuminates the fact that these two clusters are coevolving. This is not surprising given the intimately coupled function of flagella and chemotaxis within the cell.

7. Phenotype profiling

We have discussed the use of phylogenetic profiling to study the evolution of genomes and to study the coevolution of encoded proteins, yielding functional clusters and networks of clusters. A third application we review is the linking of genes to phenotypes (Jim, 2004; Levesque, *et al*., 2003).

Each of the fully sequenced organisms that is used to construct phylogenetic profiles of a gene has specific phenotypes. A phenotype is any observable characteristic of the organism. Examples of phenotypes include flagella, pili, and thermosensitivity. It is possible to construct a phenotypic profile by cataloging the presence or absence of the phenotype across genomes, just as we have done for the presence or absence of genes.

By identifying the genes whose phylogenetic profiles are correlated with the phenotypic profiles, it is possible to associate a gene with the phenotype. For instance, about half of the fully sequenced organisms contain flagella. The genes whose phylogenetic profiles are correlated with a flagella profile are nearly all known components of the bacterial flagella (Levesque, 2003; Jim, 2004). The same approach may also be used to identify the components of pili, and the proteins that endow organisms with thermostability (Jim, 2004). In general, if a reliable phenotypic profile can be constructed for a trait that is found in a significant fraction of the sequenced genomes, this technique can identify the proteins that are most likely responsible for the trait.

8. Conclusions

The availability of fully sequenced genomes has enabled us to perform phylogenetic profiling by identifying the distribution of protein families across organisms. As we have discussed in this review, phylogenetic profiling may be used to study the evolution of genomes, the coevolution of proteins or the association between proteins and phenotypes.

Today, we have access to about 100 fully sequenced genomes. However, it is reasonable to assume that within the next decade this number will grow by orders of magnitude. As the data become available, phylogenetic profiling will become far more powerful than it is today. As a result, phylogenetic profiling will undoubtedly continue to expand our understanding of genome evolution and protein function.

Specialist Review

Reconstructing vertebrate phylogenetic trees

Sudhir Kumar and Alan Filipski
Arizona State University, Tempe, AZ, USA

1. Introduction

The first major scientific figure to challenge the idea of fixity of species was Jean-Baptiste Lamarck (1744–1829), the French naturalist who in 1802 coined the term *biology*. Although his name is now most commonly associated with erroneous ideas about inheritance of acquired characters, his major contribution to evolutionary thought was his promotion of the very concept of adaptive change in lineages over long periods of time. Figure 1, from Lamarck (1809) in his *Philosophie Zoologique*, depicts a portion of the first published evolutionary tree based on a hypothesized order of acquisition of a few key characters. For example, the tree showed monotremes deriving from birds because of their egg-laying characteristic, while the two classical groups of terrestrial mammals – hoofed (e.g., cow and horse) and nailed (e.g., human and mouse) – both derived from amphibious mammals as an intermediate form. Although the depiction has some problems, as showing extant groups as ancestral to each other, and incorporating Aristotle's idea of a linear progression from simple to complex, yet it is an actual evolutionary tree as stated in its original caption "to show the origin of the different animals."

Ernst Haeckel (1834–1919), inspired by Darwin, Goethe, and Lamarck, whom he called the "three fathers of the theory of descent", coined the word *phylogeny* in his *Generelle Morphologie der Organismen* of 1866 (Haeckel, 1866) and drew hundreds of trees depicting the evolutionary relationship of organisms. Haeckel constructed them largely on the basis of his theory of progress, as revealed by his biogenetic law ("ontogeny recapitulates phylogeny") with Germanic man at the pinnacle and other lineages represented as radiating side branches. (Haeckel, 1900; Dayrat, 2003).

With the introduction of phenetics and cladistics in the twentieth century, phylogenetic analyses grew more sophisticated, with investigators abandoning the idea of man as the summit of progress in favor of the Darwinian idea of adaptive divergence along all lineages, and using a larger number of more informative characters. In particular, characters relating to the skeleton and teeth were of great value in vertebrate phylogenetics, because they are easily fossilized and straightforwardly compared in living specimens. Using shared derived characters, many monophyletic groups

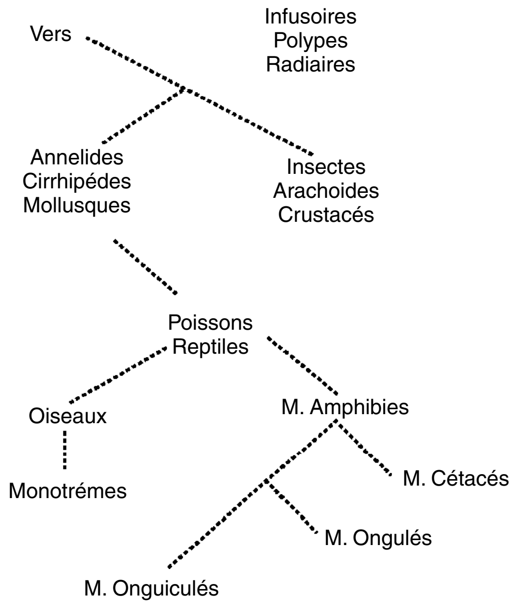

Figure 1 The first tree showing evolutionary relationships of animals, published by Lamarck (1809), including, among the vertebrates: Fish (Poissons), monotremes (Monotrèmes) birds (Oiseaux), amphibious mammals (M. Amphibies), whales (M. Cétacés), hoofed mammals (M. Ongulés), and nailed/clawed mammals (M. Onguiculés)

(groups of taxa that include all descendants of their most recent common ancestor) that are still in use today were delineated. For example, the group Tetrapoda (four-legged animals) was defined to include amphibians (e.g., frogs) and amniotes (e.g., birds and mammals) based on their many shared skeletal characteristics, such as dactyly, sacrum, stapes, and *fenestra ovalis* (Panchen and Smithson, 1988). By making successive nested groupings in this way, full phylogenetic trees have been inferred. Indeed, as data matrices have become larger, investigators have taken more algorithmic and computational approaches and increased their use of the principle of maximum parsimony.

Phylogenies based on morphological characters have clearly resolved many basic vertebrate relationships. However, some groupings have been less convincing. For example, Cetaceans (whales and dolphins), even-toed ungulates (artiodactyls), and odd-toed ungulates (perissodactyls) form monophyletic groups based on morphology, but morphological analyses did not clearly resolve their interrelationship (Novacek, Wyss *et al*., 1988). This is because in certain characters cetaceans appear to have been derived from even-toed ungulates and in others from odd-toed ungulates.

There also has been great interest in establishing a timescale of major events in vertebrate history. Although the vertebrate fossil record is the best among all known animal groups, the assignment of individual fossils into the tree based on living species is complicated and the divergence times based on the fossil record are almost always smaller than the actual time. This is because an unknown amount

of time must pass before discernibly different forms evolve, and there is a low probability that investigators will discover the earliest fossils after a divergence (e.g., Novacek, 1992; Hedges, Parker *et al*., 1996; Tavare, Marshall *et al*., 2002). For instance, fossils of placental mammals are found throughout the Cretaceous era (65–144 Mya), but identifiable members of modern orders (e.g., rodents, primates, and artiodactyls) older than the Palaeocene epoch (56–65 Mya) were found only recently (e.g., Archibald, 1996). So, although we can put a lower bound on the divergence time of these orders sometime during the Palaeocene, we cannot be sure if they existed at an earlier time (see, however, Tavare, Marshall *et al*., 2002).

While in the last decade investigations aimed at finding the relationships among species on the basis of morphological, physiological, behavioral, and other nonmolecular characters have continued to refine the vertebrate tree of life, many specific questions have remained controversial, including the interrelationship of mammalian orders. To resolve these points, molecular phylogenetics is proving invaluable (e.g., Nei and Kumar, 2000; Felsenstein, 2003).

2. The age of molecular phylogenetics

In the last decades of the twentieth century, a vast quantity of DNA and protein sequence data became publicly available, offering almost limitless opportunities for inferring phylogenetic relationships and temporal patterns of vertebrate evolution. In fact, the technological advances made in sequencing genomes, the development of sophisticated statistical and computational methods of phylogeny reconstruction, and the success of individual phylogenetic investigations in resolving long-standing issues led the National Science Foundation (USA) to initiate the Tree of Life (ToL) project to establish a phylogenetic framework (Darwin's "Great Tree of Life") for the approximately 1.75 million described species of organisms. Many groups of vertebrates are now the targets of large-scale investigations in this most promising project of modern evolutionary biology.

However, molecular data do not provide a magic lens for clarifying all phylogenetic questions, even when data are available for a large number of genes or even complete genomes. Many biological and methodological complexities affect the accuracy of the inferred phylogenies and the times of species divergence (reviewed in Nei and Kumar, 2000; Benton and Ayala, 2003; Felsenstein, 2003; Hedges and Kumar, 2003). In this chapter, we briefly discuss the techniques and data used to resolve disputed vertebrate relationships and to confirm or challenge the evolutionary trees inferred from nonmolecular data.

Figure 2 shows one view of the modern vertebrate phylogeny, with an emphasis on the evolutionary relationships of major vertebrate groups and mammalian taxa. In it, the hagfishes (Myxionoidea) and lampreys (Petromyzontoidea) form a monophyletic group, (Cyclostomata), that is an outgroup to all other vertebrates (jawed vertebrates or Gnathostomes). However, the exact topology of this deepest part of the vertebrate tree was controversial until recently. Traditionally, nonmolecular data supported the idea that Cyclostomata was a monophyletic group, but morphological analyses in the late 1980s suggested that lampreys were the closest relatives of jawed vertebrates. Then, in the early 1990s, molecular

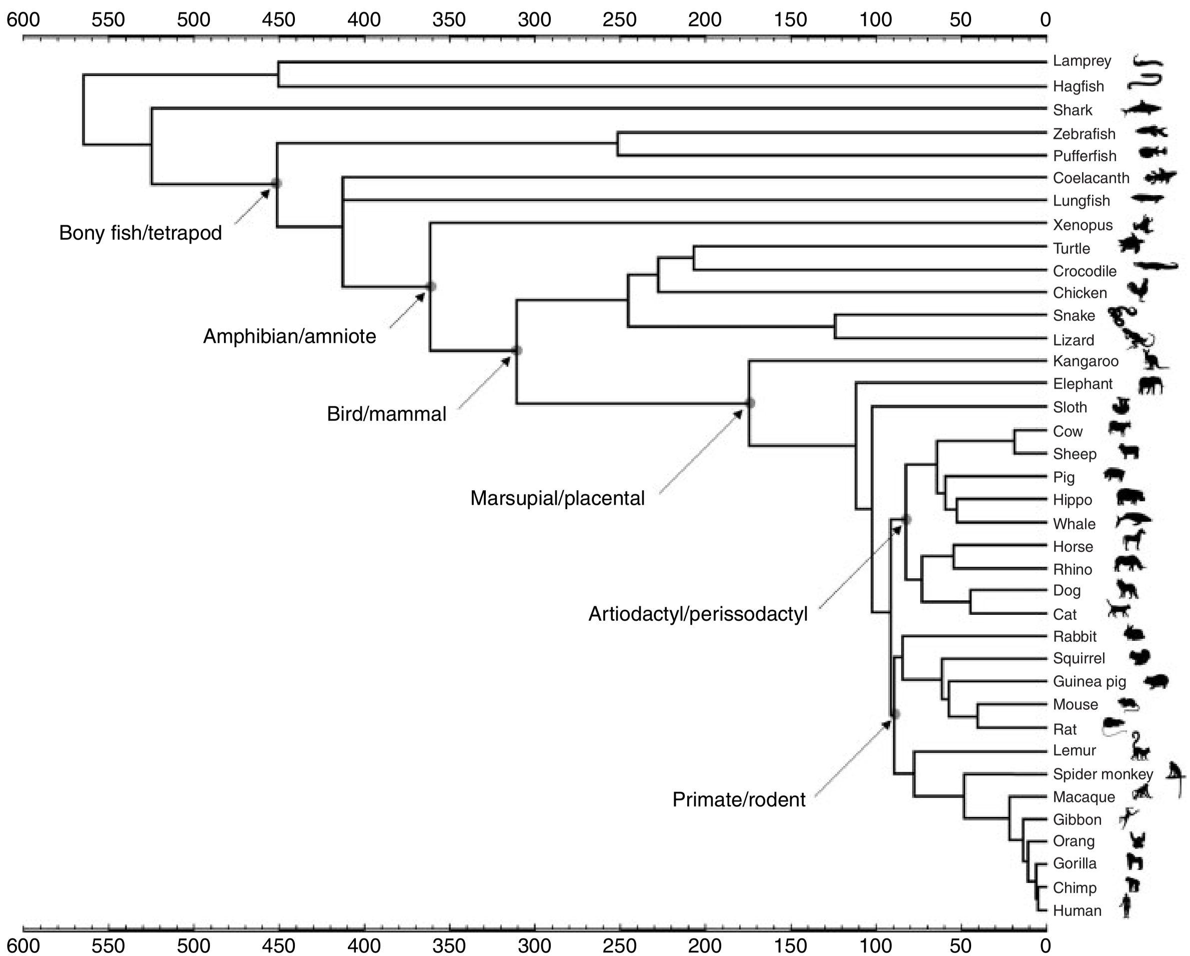

Figure 2 The current understanding of evolutionary relationship and timescale of major classes of vertebrate and groups of mammals based on fossil record and molecular data

phylogenies inferred using a single gene (18 S ribosomal RNA) again supported the traditional view of a monophyletic Cyclostomata (Stock and Whitt, 1992), although this view was not immediately accepted due, in part, to its use of only a single gene. Recent analyses of many nuclear proteins and complete mitochondrial DNA (mtDNA) have reaffirmed the monophyly of Cyclostomata (Hedges, 2001; Delarbre, Gallut *et al*., 2002; Takezaki, Figueroa *et al*., 2003).

While the cyclostome phylogeny based on the mtDNA genome agreed with that established from nuclear proteins (Delarbre, Gallut *et al*., 2002), the use of these genomes has led to suggestions that the classical position of the cartilaginous fishes (sharks and their kin) be revised (Rasmussen and Arnason, 1999). For compelling morphological reasons, the cartilaginous fishes traditionally have been placed in a basal position with respect to the rest of the jawed vertebrates (including bony fish and tetrapods). But early mtDNA phylogenies placed sharks, with significant statistical support, as a sister group to bony fish. However, a subsequent analysis of many nuclear proteins reversed the mtDNA phylogeny (Cotton and Page, 2002; Takezaki, Figueroa *et al*., 2003). This raises questions about the appropriateness of mtDNA for inferring the deepest branching patterns in the vertebrate tree. These results underscore the need for genomic data for more organisms, a more extensive analysis of statistical support, and a consideration of sources of error and biases that prevent robust molecular phylogenetic inference.

The next major divergence of vertebrates concerns the relationship of tetrapods with lungfish and coelacanth (Figure 2). The traditional view is that coelacanth and tetrapods cluster together. This is based on the inclusion of coelacanths and certain extinct fish into the group Crossopterygii, whose members share several important characters with certain early amphibians, such as limb bone patterns and labyrinthodont teeth. However, there is also some morphological support for a close association of lungfish and tetrapods. Molecular phylogenies have found support for all three configurations, coelacanth with lungfish, tetrapod with lungfish, and tetrapod with coelacanth. (Hedges, Hass *et al*., 1993; Zardoya and Meyer, 1996; Zardoya, Cao *et al*., 1998; Venkatesh, Erdmann *et al*., 2001). This trichotomy remains unresolved and will probably require much more molecular data for a satisfactory resolution. This shows that it is not easy, using either traditional or molecular methods, to resolve events that took place more than 360 million years ago within a narrow window of perhaps 30 million years. Morphological homology can become confused with homoplasy and sequence similarities can become effaced with time, especially if subsequent speciation events occur over a short time period.

The classification of mammals has occupied naturalists since the time of Aristotle. Although early taxonomists had a fairly good idea of how to partition the placental mammals into orders (rodents, primates, etc.) and superorders (e.g., Gregory, 1910), an understanding of the interordinal relationships among placental mammals and even the relation of the three main groups of mammals (placentals, marsupials, and monotremes) has remained elusive. The relation of the scuirognaths (e.g., mouse, squirrel), hystricognaths (e.g., guinea pig, porcupine), and lagomorphs (e.g., rabbit, hare) has been extensively debated for decades, recently with the publication of articles such as "Is the Guinea pig a rodent" and "What, if anything, is a rabbit?" (Graur, Hide *et al*., 1991; Graur, Duret *et al*., 1996). In both of these instances, molecular data overturned the classical relationships (see Liu and

Miyamoto, 1999), yet the use of different methods of phylogenetic inference and larger, more taxonomically dense datasets now supports the classical phylogenies (Murphy, Eizirik *et al*., 2001). Modern analyses also have placed rodents and primates as sister groups, a departure from the more basal position of rodents in the placental mammal phylogenies of the 1990s. Still, all superordinal mammalian divergences are not resolved with high statistical confidence (Scally, Madsen *et al*., 2001; Springer and de Jong, 2001).

The possibility that higher-level placental divergences occurred within a very short time period (<5 Myr) has suggested the use of alternative molecular markers to bring more data to bear on the problem (e.g., Shedlock and Okada, 2000). For instance, initial gene sequence analyses placed hippos as a sister group to cetaceans with the combined group appearing as a sister lineage to the ruminants within Artiodactyla (Gatesy, 1997; Gatesy, Milinkovitch *et al*., 1999). However, the widespread acceptance of this scheme came about only after a cladistic analysis of SINE elements, the short sequences of 80–400 nucleotides that appear as repeats in the genome (Shimamura, Yasue *et al*., 1997; Nikaido, Rooney *et al*., 1999). Recent fossil discoveries support this reevaluation of the relationships of hippos, cetaceans, and artiodactyls (Thewissen and Madar, 1999; Thewissen, Williams *et al*., 2001).

A useful feature of molecular phylogenetics is its ability to assign dates to speciation events. Although the rates of molecular evolution vary greatly for different kinds of sequence data and for genes under different selective constraints, it is possible to identify and test data sets for a constant rate of evolution (molecular clock property), and sequences that deviate from this standard may be excluded. If we obtain one or more calibration points – divergence times in a tree whose date is confidently known – then the molecular evolution rate can be established and all divergence events in that tree can be dated. In addition, sophisticated methods of incorporating complex models of DNA and protein evolution and distributions of evolutionary rates along lineages are now available (see review and references in Hedges and Kumar, 2003). These molecular timescales complement those based on the fossil record and many molecular-based estimates show excellent correspondence with fossil-based estimates (Kumar and Hedges, 1998); however, others show significant differences, with molecular time estimates being considerably larger in some cases. For instance, initial molecular clock studies suggest that major orders of mammals diverged more than 90 Mya (Hedges, Parker *et al*., 1996; Kumar and Hedges, 1998) and that continental breakup, rather than the dinosaur extinction's vacating of ecological niches for mammalian radiation, may be the primary mechanism. Such estimates have been confirmed in subsequent analyses, which have used different datasets and statistical methodologies (Springer, Cleven *et al*., 1997; Hasegawa, Thorne *et al*., 2003). On the other hand, the discrepancy between the molecular evolutionary timescales within rodents (e.g., mouse–rat divergence), which indicate a much older divergence than suggested by the fossil record (>30 Mya versus ~12 Mya) has recently been revised, bringing both molecular divergence estimates much closer to the fossil record (Easteal, 1990; Kumar and Hedges, 1998; Springer, Murphy *et al*., 2003; Hedges and Kumar, 2004). Thus, more extensive molecular clock analyses are in some cases confirming early divergence estimates based on small data sets, and, in other cases, reconfirming fossil-based estimates.

While the value of using molecular data to discern evolutionary relationships and timescales is clear, the design of the analysis is important. Some guiding principles that can be useful in generating more robust results, based on our personal experience, are as follows. First, it is necessary to use as much data as possible. It is particularly important to use all possible genes for which data are available for all taxa (see results and references in Rosenberg and Kumar, 2001a,b; Hillis, Pollock *et al*., 2003; Rosenberg and Kumar, 2003). It is also important to use a large number of species per group, especially when there is a possibility of long-branch attraction (Felsenstein, 1978) or of evolutionary rate speed-up in some lineages (Springer, Murphy *et al*., 2003). To accomplish this, multiple genes or other homologous regions can be combined by simple concatenation (e.g., Rokas, Williams *et al*., 2003), although it is then necessary to account for rate variation among sites and to use gene-specific nucleotide and protein substitution matrices (e.g., Nei, Xu *et al*., 2001; Springer, Murphy *et al*., 2003). Second, only orthologous gene sequences can be used to represent species, that is, they must derive from speciation events and not gene duplications. This is crucial for both molecular phylogeny as well as time estimation. Third, it is important to realize that there are no invincible methods for phylogenetic inference (Nei and Kumar, 2000). Generally, it is important to try several applicable methods and look for congruence (although congruence should not be taken as a necessary predictor of accuracy of the inferred phylogenies, but used to pursue method-specific biases that might be responsible for some observed branching patterns). Such efforts are, however, often hampered by the number of species in the datasets, because very large scale analyses are cost prohibitive for methods other than the neighbor-joining method (Saitou and Nei, 1987; Tamura, Nei *et al*., 2004) or fast heuristic searches under maximum likelihood and parsimony. Fourth, when examining the robustness of the inferred phylogeny, it is important to use approaches such as the bootstrap method to generate conservative estimates of statistical support (reviewed in Nei and Kumar, 2000; Felsenstein, 2003). Fifth, the timing of phylogenetic events should be determined by using one or more highly constrained and reliable reference times for calibrating molecular clocks. Also, a variety of statistical methods should be used to account for rate variation among lineages, either eliminating them by using relative rate tests (Wu and Li, 1985; Takezaki, Rzhetsky *et al*., 1995; Kumar and Hedges, 1998) or by explicitly modeling lineage-specific rate variations (e.g., Thorne and Kishino, 2002; Hasegawa, Thorne *et al*., 2003).

Molecular sequences provide a vast new data stream for vertebrate phylogenetics. These data complement and provide reciprocal validation for analyses based on morphological data. Although morphological data are more easily available for long-extinct taxa, molecular sequence analyses can provide a new view of divergence times and can assist with the resolution of some important questions. Indeed, phylogenetic analysis based on molecular sequence data seems poised to address many of the long-standing and difficult problems of vertebrate phylogenetics. At the same time, molecular phylogenetics is becoming increasingly important in a broader sense as it informs biological application areas such as medicine, animal husbandry, and conservation biology. We now have complete sequenced genomes for human, mouse, dog, rat, chimpanzee, chicken, and several fish, with many more vertebrates in the pipeline (see review in Filipski and Kumar, 2004). Although we

have identified and located many genes in these species, our understanding of the location and nature of the critical control regions in these genomes that direct gene interaction and regulate expression and development is still quite limited. For such purposes, comparative genomics from an evolutionary perspective is essential (Hedges and Kumar, 2002; Thomas and Touchman, 2002). An important factor in deciding which genomes to sequence next is the question of which ones will best contribute to our understanding of the function and evolution of the human genome (Thomas, Touchman *et al*., 2003). Reciprocally, as more genomes are mapped, knowledge of the function of homologous areas in related genomes can be applied, for example, to animal husbandry and the identification of genes of agricultural importance. Recently, for example, sequencing project for the cow genome has begun (Lewin, 2003). Besides the obvious agricultural applications relating to milk and beef production, this genome will provide a useful comparison to the human genome, as a relatively closely related mammalian relative. Therefore, as more molecular sequences and the tools to analyze them become available, the associated improved understanding of evolutionary relationships will continue to help guide both pure and applied biological research.

Specialist Review

Evolution of regulatory networks

Erich Bornberg-Bauer and Amelie Veron
The Westphalian Wilhelm's University of Münster, Münster, Germany

1. Introduction

Recurrent development of similar morphological features in response to evolutionary adaptation are often seen as a prime challenge in explaining the evolution of biological complexity. One well-known example is the camera eye. In essence, it has a similar construction scheme in the octopus and in higher vertebrates but does not exist in the last common ancestor. Other examples are the repeated adaptation of fish, saurian, birds, and mammals to life in water resulting in similar streamline shape and fins, or the repeated development of wings from the frontal limbs in birds and bats. These events are often termed phenotypically convergent evolution and can be seen as an incarnation of Gould's metaphoric question of "What would be conserved if the tape were played twice" (Gould, 1989). Computer experiments at the level of an abstract chemistry (Fontana and Buss, 1994) and the simulation of primordial evolution in an RNA world (Fontana and Schuster, 1998) showed that similar complex structures may repeatedly arise under evolutionary pressure, when starting from completely different initial conditions.

However, organismal development is more difficult to understand since it depends on many conflicting fitness parameters. It is intimately related to genetic regulation since, for example, organisms or metabolic response require the concerted action of not just one but many regulatory proteins. *So, how then does genetic regulation evolve?*

In Eukaryotes, gene regulation happens predominantly at the level of transcription and the number of transcription factors increases from a few hundred in Bacteria such as *Escherichia coli* to well over 3000 in humans (Levine and Tjian, 2003; van Nimwegen, 2003). Consequently, the number of genetic circuits or regulatory networks that arise as a result of the combinatorics, also increases. Therefore, minor changes in single genes may well propagate along such networks and may have, in the end, quite drastic effects on gene expression in response to external stimuli and during development. But how do these changes occur, considering that the emergence of, for example, new organs requires the concerted interplay between many transcription factors and with their binding sites during development? Do networks evolve in big leaps, for example, by duplicating a whole module during a genome duplication? Do new transcription factors always emerge together with their up- and downstream binding sites?

Here we summarize briefly some of the most recent insights from genomics, proteomics, and transcriptomics studies on regulatory network evolution. We break the subject down into sections covering the evolution of transcription factors and their domains, binding sites, their coevolution and the graph-based "global" analysis. Owing to space limitations and the fuzziness of available information, the section on promoter evolution will be kept very brief. We close with some speculations that attempt to provide a coherent picture on how complex networks may have evolved. It can only be preliminary since the field is moving rapidly. Therefore, much caution is required in the interpretation of findings and current knowledge and technologies are just about to reveal a comprehensive picture.

2. Definitions

At a most basic, conceptual level, a regulatory network consists of three components (see also Figure 1):

1. the transcription factor (TF), or its gene itself;
2. the upstream-regulatory region on the DNA by which (through another transcription factor) transcription of the gene is mediated;

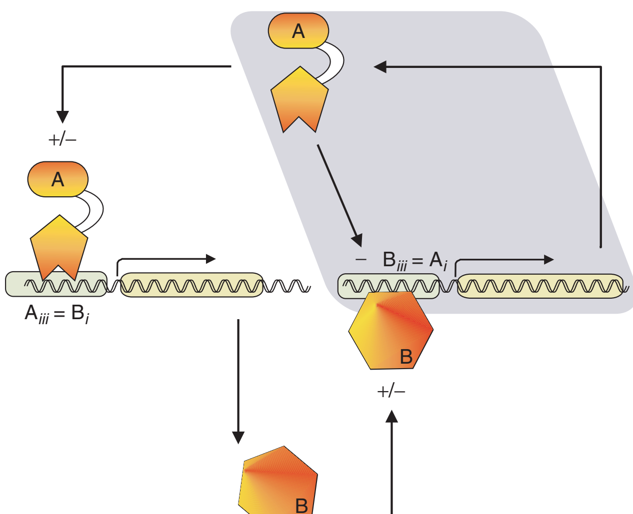

Figure 1 Schematic drawing of the basic construction principle of an elementary unit of a hypothetical genetic regulatory network: Transcription factor *A* (a two-domain protein) binds to its downstream binding site A_{iii}, which is also the upstream binding site B_i for transcription factor *B*, transcribed from gene *B*. *B* (orange hexagon) in turn acts on the binding site ($A_i = B_{iii}$). This gives a simple 2-component regulatory networks. It has a feedback structure with many possible variations since either binding can activate or repress transcription or both, depending on physiological conditions. When *A* also binds to its own upstream-regulatory region, for example, as a repressor blocking its own transcription and competing with *B* of binding to A_i, this results in a negative autoregulatory feedback loop. A single, autoregulatory negative feedback loop is shaded grey. The activity of *A* may be further regulated by stimuli, for example, via signaling pathways acting on the secondary regulatory domain

3. the regulatory region to which the transcription finally binds to, the downstream-binding region.

As we will detail later on, these links are mostly one-to-many, that is, each transcription factor regulates more than one gene and most genes are controlled by some, albeit generally few, transcription factors. Every transcription factor, with the exception of maternal transcription factors, is itself regulated by another one. This combinatorics gives rise to quite complex regulatory networks.

Each of these elements can be decomposed into subelements. For example, regulatory regions are often modular. The transcription factor itself typically contains a DNA-binding domain, and other regulatory domains. These are dimerization domains to form homo- or heterodimers and other protein interaction domains that mediate interaction with other proteins such as signaling proteins in order to react to physiological or environmental changes.

3. Evolution of transcription factors

3.1. Evolution of DNA-binding domains

Generally, the DNA-binding domains are among the most ancient domains, and they are derived from a relatively small set of folds (Perez-Rueda and Collado-Vides, 2000; Aravind and Koonin, 1999; Riechmann *et al*., 2000; Babu *et al*., 2004). These domains can thus be used to define protein families. They are differentially combined with other domains (Amoutzias *et al*., 2004a; Ledent and Vervoort, 2001; Morgenstern and Atchley, 1999). Examples are the families of bZIP proteins and NR (nuclear receptors), which comprise an ancient DNA-binding domain and some additional domains (see Table 1). Another, slightly more involved example is the family of bHLH transcription factors. There, the DNA-binding basic region is adjacent to the HLH domain. It is an ancient homo- and heterodimerizing domain and defines the family. The combination of additional domains (basic DNA-binding domain, leucine zipper, PAS or orange, see Figure 2) defines the monophyletic subgroups with distinct functions, many of which resemble organismal development and have emerged subsequently during evolution.

At least for most TFs in *E. coli* (Babu and Teichmann, 2003) and for bHLH, NR, and bZIP proteins (Amoutzias *et al*., 2004a,b), it was shown that their major means of proliferation was single-gene duplication of one ancestral protein, that is, they are monophyletic. Many TF families have spread over all major kingdoms but there are remarkable characteristics (see Table 1): some TFs appear mainly in Bacteria, like numerous Helix-Turn-Helix (HTH) families (Huffman and Brennan, 2002); some, although found in all metazoan, have particularly spread in some phyla such as the nuclear receptors, which are very frequent in *C. elegans* (Sluder *et al*., 1999) and Zn_2/Cys_6-type zinc cluster, which is restricted to fungal genomes (Akache *et al*., 2001). The MADS-box genes, only present in the Eukarya, were duplicated before the plant-animal divergence (Alvarez-Buylla *et al*., 2000). Both subsequent types of genes are found in all Eukarya, but in plants, the type II genes

Table 1 Occurrences of DNA-binding domains of transcription factors across taxa as defined in Pfam version 16.0 (Reproduced from Bateman *et al*. (2004) by permission of Oxford University Press)

Domain name	*E. coli*	*S. cerevisiae*	*C. elegans*	*D. melanogaster*	*H. sapiens*	*A. thaliana*
Homeodomain[a]	0	22	147	300	533	224
Nuclear receptors[b]	0	0	363	46	132	0
Zinc finger[c]	3	4	233	597	1574	512

P53	0	0	1	3	29	0
Runt	0	0	1	13	3	0
Paired box (PAX)	0	0	16	18	22	0
Myb-like DNA-BD	0	16	22	44	102	604

[a]Homeodomain: homeobox, POX, POU, TF_Oxt, HD_ZipN, OAR, PBX, PHD, ELK, CUT.
[b]Nuclear receptors: FTZ, Zf_C4, Androgen Oestrogen, Glucocorticoid, Progesterone.
[c]Zinc finger: GATA, CBFD_NFYB_HMF, zf-CCHC, zf-CXXC, C2 H2, zf-Dof, zf-MIZ, zf-NF-X1, zf-DBF.
[d]Basic leucine zipper: bZip_1, bZip_2 and bZip_Maf.
[e]Helix-Turn-Helix: iclR, DeoR, HTH_1,2,3,5,6,8, lacI, Crl, LexA DNA-BD, AbrB-like, gntR, MerR.
[f]Winged Helix-Turn-Helix: subfamily of the HTH (Huffman and Brennan, 2002), fork-head, ETS, MarR, E2F, LytTr, and La.

have particularly proliferated, giving rise to the flourishing MIKC family (Becker and Theissen, 2003).

Generally, the distribution over Bacteria is more even than over Eukarya. This has been interpreted as a result of frequent horizontal transfer (Lespinet *et al*., 2002; Coulson *et al*., 2001; Babu *et al*., 2004). In Eukarya, there exist around 12 to 15 families according to structural classification of the DNA-binding domain. The most frequent family in Eukarya are the zinc-fingers. They are strongly overrepresented in animals and plants.

3.2. *Evolution of dimerization domains*

Many transcription factors bind to DNA-binding sites as dimers. Notwithstanding the debate whether dimerization precedes DNA binding or vice versa, the resulting network is particularly interesting since it can be studied by phylogenetic trees and abundant protein-interaction data (Amoutzias *et al*., 2004a). In the family of bHLH, proteins members of the “D-group” act as modulators. They have a dimerization (HLH) domain but no DNA-binding domain. Therefore, they can act as repressors by deactivating the dimerization partner. Both from reasoning and from phylogenetic profiling, it was concluded that the ancestral proteins are probably the homodimerizing ones (Amoutzias *et al*., 2005). They have proliferated through series of single-gene duplications. This gave rise to a complex interaction network with the descendant of the ancestral proteins becoming the hubs.

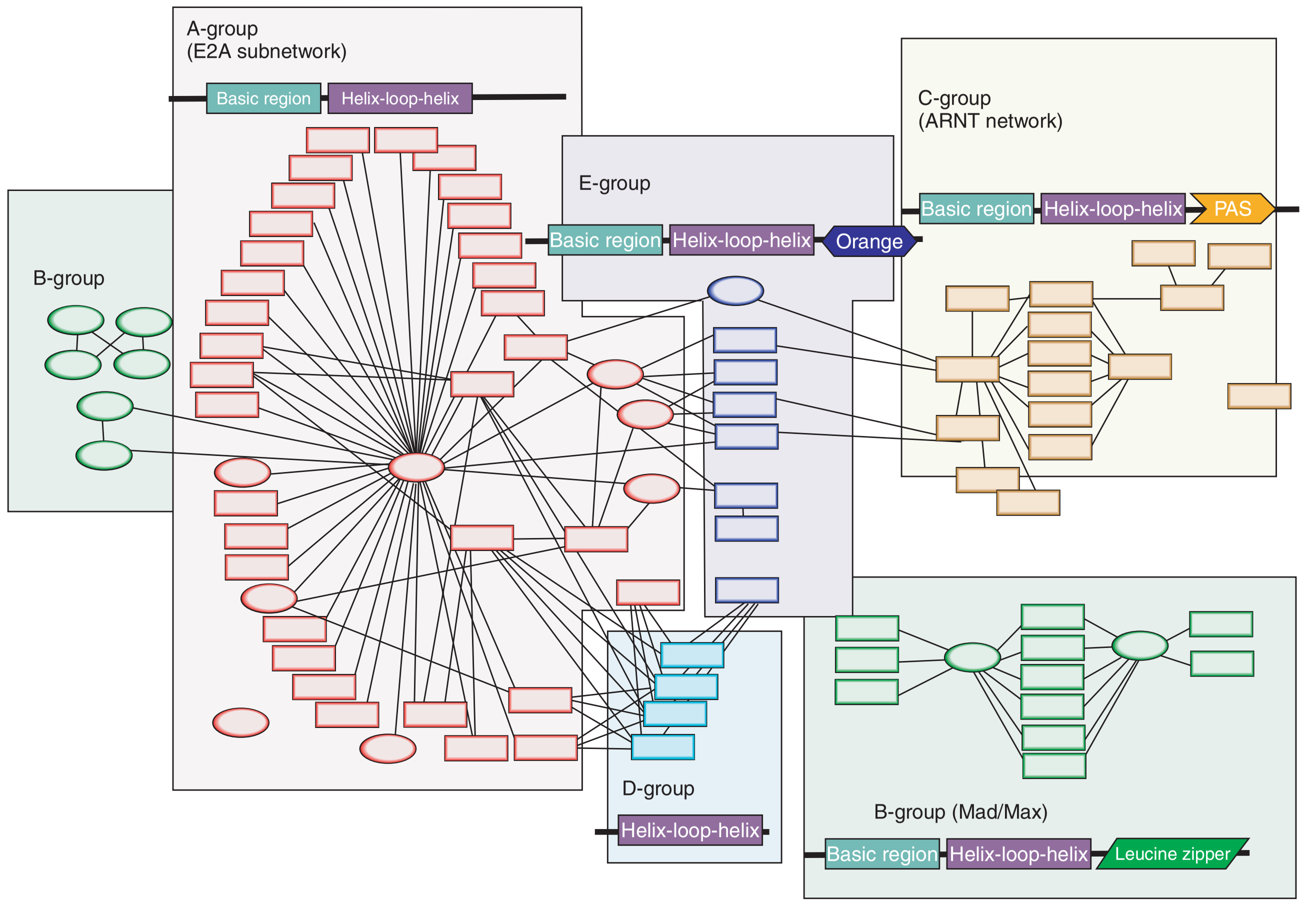

Figure 2 **Schema of the protein-interaction network of bHLH proteins**. Homodimerizing proteins are drawn as ellipses, heterodimerizing ones as rectangles, and heterodimerizing interactions as connecting lines. All data are based on multiple sources of information as described in Amoutzias *et al*., (2004a,b), Amoutzias *et al*. (2005) and available on **www.uni-muenster.de/Biologie.Botanik/ebb/html/research/AROB-EMBO-031210-supplementary-material.pdf**. Some proteins appear as hubs and, typically, they are descendants of ancient homodimerizing proteins. The corresponding domain architectures are given in corresponding boxes. Each group has evolved separately from an ancestral gene, primarily through series of gene duplication (Reproduced from Amoutzias *et al*. (2004a), Bornberg-Bauer *et al*. (2005) by permission of Birkhäuser Verlag AG. Copyright Birkhäuser Publishing Limited, Basel, Switzerland)

Evolution of dimerization domains allowed the MADS-box genes to interact with many different partners and achieve a specificity for the target gene and physiological conditions. A large proportion of animal and fungal MADS-box genes interact with phylogenetically unrelated partners such as homeodomain or zinc-finger proteins, while plant MADS-box genes form higher-order complexes, mainly with closely related transcription factors, that is, other MADS-box genes (Messenguy and Dubois, 2003). Multimerization of some plant MADS-domain proteins (termed MIKC-type) may have been facilitated by the acquisition of a second protein-interaction domain during evolution (Kaufmann *et al*., 2005).

3.3. Evolution of effector domains

Generally, effector domains are domains that relay a signal, for example, from a signaling pathway, to the DNA-binding property of the TF.

To the best of our knowledge, no studies so far have linked genetic networks and their regulation with other interactions such as signaling pathways, although many effector domains are protein-interaction domains. However, the aforementioned studies (Amoutzias *et al*., 2004a) have suggested that in the bHLH system, the loss (leucine zipper) and accretion (PAS, Orange) of domains has supported the structural differentiation of duplicated genes. As a consequence, these proteins lost their binding ability to their parental network and became free to differentiate into their own networks. In other words, the domain architecture mediates structural changes that help to form networks.

Nuclear receptors contain, apart from the DNA-binding domain (DBD), an effector domain that binds ligands (LBD) such as hormones as external signals. This domain binds, for example, steroids tightly and specifically in response to a hormone signal, which has migrated to the nucleus. A structural change in this LBD induces a structural change in the DBD, activating or deactivating its regulatory function (DNA binding). Lacking the signal, NRs are inert or repressors. According to phylogenetic analysis and structural considerations, some LBDs have probably lost their ligand binding ability during evolution (Schwabe and Teichmann, 2004).

3.4. Evolution of cofactors

Cofactors are, for example, ligands or other proteins that mediate transcriptional activity via interaction, either directly or indirectly, with the TFs. They confer time and gene specificity, and can be seen as the bearers of news from the outside world, bringing them to the transcription factors. They can modify the effector or the DNA-binding domains of their target transcription factors (Messenguy and Dubois, 2003) or trigger their migration from the cytoplasm to the nucleus (Kawana *et al*., 2003). Generally, only very few systematic results on this aspect have been disseminated, probably because of the tight involvement with metabolic pathways, signaling pathways and signaling molecules.

The cofactors could consequently play a role in linking different networks, such as the LIM proteins, which interact with bHLH and zinc-finger transcription factors,

protein kinases, and numerous other types of proteins (Matthews and Visvader, 2003).

Transcription factors, such as the above-mentioned D-group of the bHLH proteins, can also be viewed as cofactors because they block other bHLH proteins through dimerization (see Figure 2).

The function (activator or repressor) and strength of a transcription factor can change according the interacting partners, be they cofactors or other TFs. The information contained in these interactions is integrated by the modules composing the promoter regions of the target genes (Wray *et al*., 2003; Emberly *et al*., 2003).

4. Evolution of promoters

Unlike coding regions, the evolution of upstream-regulatory regions cannot be easily evaluated by means of sequence alignments and comparisons. Indeed, the structure, organization, and function of promoters differ widely from that of the coding sequences, resulting in totally different evolution rates and consequences of sequence variation (Rodriguez-Trelles *et al*., 2003). Generally, promoter organization underlies more variation than the organization of coding sequences and is more context dependent. It is influenced by DNA structure (Wang *et al*., 2004) and other epigenetic effects such as chromatin structure (Bode *et al*., 2003), competing binding events, neighborhood relations on the DNA, availability of the appropriate cofactors, and so forth (for a comprehensive review, see (Wray *et al*., 2003). Eukaryotic promoter sequences, or upstream-regulatory regions, contain numerous transcription factor binding sites (TFBS), and are typically a few hundred bp to more than 100 kb long. Within these regions, only 10 to 20% of the nucleotides actually are TFBS. Most binding sites range only 5–8 bp and are grouped into functional modules (Yuh *et al*., 2001). These modules are interspersed with regulatory regions that contain no binding site.

Several transcription factors and cofactors often interact in alternate combinations, depending on signals and physiological or environmental requirements. This gives rise to activating or repressing complexes and requires a modular organization of the binding sites (Messenguy and Dubois, 2003). However, even regions without TFBS may influence the local DNA conformation and modulate interactions within or in between such modules (Wray *et al*., 2003).

While the genetic operations acting on DNA are the same for coding and non-coding regions, the complexity of promoter organization induces different selection criteria since consequences of mutations on organismal development are different (Rodriguez-Trelles *et al*., 2003). Systematic studies are rare due to the aforementioned involvement of subtle signals and context dependency. While, for example, only ≈2–3% of expression variation in yeast duplicates can be explained by motif divergence in upstream-regulatory regions (Zhang *et al*., 2004), point mutations in essential binding sites can have consequences on the phenotype, all the more if the target gene is a transcription factor itself (Carroll, 2000). Different phenomena can explain this apparent contradiction. Compensatory mutations in binding sites or modules have been shown to exist by Tautz and coworkers (Tautz, 2000). Moreover, not all TFBS computationally identified are functional, and subsequently have less

importance for gene regulation (Rodriguez-Trelles *et al*., 2003). Mutations within the modules can modify the affinity of a binding site for its ligand(s), or might even create or delete binding sites resulting in modified transcription profiles that are specific for the affected module and conditions while mutations in coding regions will always be expressed the same (Wray *et al*., 2003).

The regulation of transcription factors plays a key role in morphological diversity. This is illustrated by *Hox* genes, which govern early organismal development. Their regulation is spatially diverged between species (Carroll, 2000). Simple modifications within the upstream-regulation region of TF can explain both minor and major changes between species, without involving any disruption of gene structure, contrary to what would occur in the effector genes (Carroll, 2000). Therefore, evolution of regulatory regions is thought to be a major source of diversity.

Some more general principles were inferred from studies on large-scale "omics" data. When a target gene is duplicated it will only be of use if it also has a functioning regulatory region. Unless it has been copied together with its previous regulatory region (or is copied accidentally into a position of another transcribed region), it will be inert and thus rapidly become a pseudogene. Consequently, target genes with a close homology (as inferred by sequence similarity) can be expected to have a tendency to be more strongly coregulated than those that have drifted more away since, on average, promoter changes will be correlated with genetic drift. Indeed, a positive correlation is observed between the degree of sequence similarity and the coregulation of two duplicated genes (van Noort *et al*., 2004). This has been explicitly shown for yeast target genes that are controlled by the same TFs (Papp *et al*., 2003; Maslov *et al*., 2004). The yeast coexpression network properties have been successfully explained on the basis of this model of coduplication of genes with their TFBSs, deletion and duplication of individual TFBSs and gene loss (van Noort *et al*., 2004).

5. Coevolution and decoupled evolution

From the standpoint of the neutral theory, it is expected that a universally valid and exact molecular clock would exist if, for a given molecule, the mutation rate for neutral alleles per year were exactly equal among all organisms at all times (Gojobori *et al*., 1990). On the basis of this assumption, Wagner tested for a correlation between divergence in sequence and divergence in expression patterns, and found that there was no significant association for yeast duplicates (Wagner, 2000). More recent studies, using more comprehensive data sets (Hughes *et al*., 2000; Lee *et al*., 2002), suggested that a positive correlation existed between sequence similarity of duplicated genes and their coexpression (van Noort *et al*., 2004).

Another study by the same group (Snel *et al*., 2004) combined coexpression and TFBS data, revealing a high conservation of gene coregulation between *C. elegans* and *S. cerevisiae*. It was observed that, in the case of a gene duplication in one of the species, only one of the duplicated genes had a conserved coexpression. Snel *et al*. (2004) then proposed a model for gene duplication in which one copy would maintain the relations of the ancestral gene, while the other would be "free" of selection constraints and could differentiate and/or undergo subfunctionalization.

Recently, the question of how network genes diverge in their transcriptional regulation after duplication was asked and tested (Evangelisti and Wagner, 2004) on the basis of the data set by Lee *et al*. (2002). The authors found that divergence after duplication is often rapid and that there is a frequent net loss of TFBS. However, this study has to be balanced with the observation that although the number of shared modules decreased, the number of modules in regulatory regions of duplicated genes in yeast is stable whatever be the age of the duplication event (Papp *et al*., 2003).

Evolution of regulatory units are extensively studied in Bacteria, but transferring this knowledge to Eukarya is problematic since eukaryotic regulation is more complex (in particular, as much as the binding sites are concerned), and the high frequency of horizontal gene transfer in Bacteria has a strong influence on network organization (McAdams *et al*., 2004).

6. A more holistic perspective: motifs, modules, and graphs

As a consequence of the abundance of data which became recently available, the idea has emerged to conceptualize genetic networks as directed graphs with nodes corresponding to the transcription factors linked by edges to their target genes.

The above-mentioned most basic elements (TF, upstream-binding site, downstream-binding site) can be combined into a next higher level, so-called network motifs (Guelzim *et al*., 2002; Babu *et al*., 2004; Shen-Orr *et al*., 2002). Probably, the most basic motif is the autoregulatory loop (see Figure 1, shaded box): a transcription factor regulates its own expression. In particular, for the inhibition autofeedback loop, Becskei and Serrano (2000) have elegantly shown in theory and experiment that it is an important basic building block enabling stability against perturbation. Generally, these motifs should not be seen as separate units of transcription since they often overlap (Dobrin *et al*., 2004) but rather as basic architectures with a certain response behavior. For example, the feed-forward loop (FFL, see Figure 3, also known as oriented triangles (Guelzim *et al*., 2002)) was shown experimentally to be designed such that noise from the upstream signals is eliminated while there is still rapid response to the target genes (Mangan *et al*., 2003).

Alon and coworkers have investigated the structure of both genetic and protein–protein interaction networks using graph analysis algorithms (Yeger-Lotem *et al*., 2004). As a main conclusion, they found that certain topologies of small subnets are statistically very much overrepresented (Shen-Orr *et al*., 2002; Lee *et al*., 2002).

Conant and Wagner have followed up this idea and introduced the notion of common ancestry for gene circuits or motifs: two motifs share a common ancestor if every pair of genes in the two circuits is derived from a common ancestor: all pairs in the circuits must be duplicated genes (Conant and Wagner, 2003). Finding that essentially no pair of motifs with identical topology had common ancestry, they concluded that their emergence is the result of convergent evolution and not duplication of one or a few ancestral circuits, and noted that convergent evolution was more likely to be important in module topology than in protein sequence

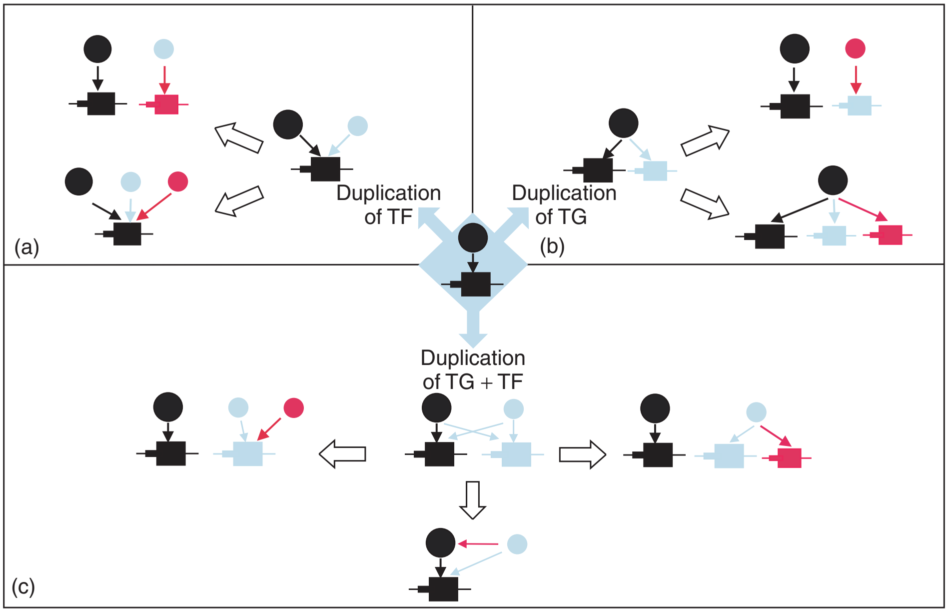

Figure 3 Growth and evolution of regulatory networks by duplication. The circles represent transcription factors (TF), the rectangles stand for the target genes (TG), the thin arrows symbolize regulation, the thick ones represent evolution. Light blue elements are duplication events and products (which are paralogous to their black counterparts), and red symbolizes gain of interaction (generally, this gain can happen by another duplication, except when mentioned). Initially, the basic unit (1st level) of the network is the pair TF/TG (in the center, light blue background). Three kinds of duplication can occur. (a) Duplication of the TF: the TG is regulated by both TF immediately after duplication, in a competitive way. The duplicated TF can then lose its affinity for the TG and gain a new one (red, top). Another solution is the gain of new TF binding sites in the promoter region of the TG, which could lead to the recruitment of yet a third TF, and form a Multiple Input Motif (MIM) (red, bottom). (b) Duplication of the TG: both TG are then regulated by the same TF. Eventually, the duplicated TG can lose its TFBS for the initial TF and gain a new one (red, top); or a third TG could join the motif, thus creating a SIM, a Single Input Motif (red, bottom). Motifs are the 2nd level of regulatory networks. (c) Duplication of both the TF and the TG: immediately after the duplication, both TF regulate both TG. This particular motif is also a MIM, but more closely connected that the one in (a). Through loss and gain of interactions, the new pair can acquire a new TF (red, left), of a new gene (red, right). Finally, after subsequent loss of interaction, if one of the TF acquires a TFBS corresponding to its duplicate (this cannot come from a duplication process), the bottom motif can appear, forming a FFL, or Feed-forward Loop (bottom) (Reproduced from Teichmann and Babu (1999) by permission of Nature Publishing Group)

(Conant and Wagner, 2003). Intuitively, such a conclusion suggests that there is a positive selection on these motifs.

The possible scenarios for the evolution of elementary networks, such as motifs, require the investigation of loss and gain of interactions in terms of duplication or coduplication of transcription factors and target genes as Teichmann and Babu (2004) have elaborated in a seminal paper. Duplication of a target gene alone will result in two genes (co-)controlled by the same TF, duplication of the TF alone will mean the target genes are controlled by the two TFs while coduplication will lead to genes coregulated by both TFs (see Figure 3). Changes in sequences of regulatory regions and/or binding domains or secondary domains will then remove or add further links. Clearly, these basic mechanisms will lead to SIMs and MIMs,

while FFLs require different mechanisms such as the gain of a new module in the promoter of a preexisting gene (see Figure 3, also for definitions). Intuitively, one might assume that the aforementioned observation of convergent motif evolution indicates that they have arisen predominantly by duplication of the whole unit. However, although many (≈45%) of the regulatory interactions in *E. coli* and yeast have arisen by gene duplication and conservation of the corresponding interactions (Teichmann and Babu, 2004), the main mechanisms of generating motifs are frequent losses and gains of interactions following the more elementary events mentioned afore (van Noort *et al*., 2004).

The third level of network organization according to Babu *et al*. (2004) comprises transcriptional modules. These are collections of motifs that are fairly independently regulated. They correspond to functional units as has been concluded from several studies using expression data (Lee *et al*., 2002). Modules represent collections of transcription factors that are expressed under distinct experimental conditions (Ihmels *et al*., 2002) and largely controlled by one (or very few) regulators as was shown by hierarchical clustering of expression profiles (Segal *et al*., 2003). Tavazoie *et al*. (1999) showed experimentally that the clusters of coexpressed genes largely correspond to sets of genes with similar function according to database classifications.

It is worthwhile noting here that modules of networks have also been identified for metabolic pathways, however, in terms of smallest stoichiometric units that cannot be further decomposed (Schuster *et al*., 2000; Schilling and Palsson, 1998) and can be defined for signaling pathways as well. Future research will show if these units refer to evolutionary related units and if their genes, too, are highly coregulated. For metabolic pathways, genomic clustering indicating strong evolutionary relationship has been shown (Lee and Sonnhammer, 2003).

For genetic networks, first indirect evidence of common evolutionary origin was provided by Schwikowski *et al*. (2000) who showed that functionally related proteins tend to have overrepresented protein–protein interactions and that most interactions are confined to proteins acting in the same cell compartment, including the nucleus and the transcription factors contained therein.

We can now return to one of the initial questions on convergent evolution of the camera eye. A recent study based on EST data suggested that in spite of differences in the actual topology, eye development in both organisms is controlled by sets of pairwise homologous genes although they are not involved in eye development in the common ancestor (Ogura *et al*., 2004). Assuming now that these regulatory genes correspond to modules in the sense mentioned above (which remains to be proven) and are controlled by few transcription factors, it is conceivable that the modules arose repeatedly from this (or these) ancestral gene(s) through the mechanism outlined above.

Further analysis of global features of genetic networks and protein-interaction networks were done on the basis of concepts borrowed from graph analysis and has revealed a scale-free topology (Barabasi and Albert, 1999; Barabasi and Oltvai, 2004). This means there are few genes, so-called hubs, controlling many others and many genes with only few links. However, regulatory networks are dynamic: it was shown that large-scale topological changes happened in the yeast genome and that although a few TFs serve as permanent hubs, most act transiently only during

certain conditions (Luscombe *et al*., 2004). The formula $C_I = \frac{2n_I}{k(k-1)}$, defines a clustering coefficient, where n_I is the number of links connecting the k_I neighbors of node I to each other (Barabasi and Oltvai, 2004). A value close to 0 with many neighbors indicates a hub, a value close to 1 a cluster. Protein-interaction networks are very useful since they can help investigate networks emerging from dimerization and secondary regulatory domains of TFs. In contrast to gene-regulatory networks, they induce nondirected graphs.

Observing the directed graph of gene-regulatory networks in yeast (Guelzim *et al*., 2002) from two distinct perspectives revealed a fundamentally different behavior of the two subgraphs : (1) the graph of incoming interactions, that is, the population of target genes being regulated by transcription factors, where the degree of connectivity (in-degree) is the number of regulatory proteins binding to a promoter region and (2) the graph of outgoing interactions, that is, the population of transcription factors regulating target genes, where the degree of connectivity (out-degree) is the number of target genes to which a transcription factor binds. It appears (Guelzim *et al*., 2002) that the in-degree has a very narrow distribution: around the mean number of transcription factors, the probability decreases with an exponential rate (nearly all target genes have the same number of transcription factors), while the out-degree has a broader distribution and follows a power-law.

Knockout studies in yeast suggested that target genes regulated by more than nine TFs are, in general, less essential (they contain proportionally less lethal genes), while the most important transcription factors are the ones binding the most target genes (Yu *et al*., 2004).

It is also worthwhile noting that more complex organisms have a higher number of regulatory genes per target gene (van Nimwegen, 2003), suggesting that it is mostly the evolution by duplication and diversification of transcription factors and of their interactions that increases organismic complexity as a whole.

7. Evolution of expression

The observation, in numerous rescue studies, that orthologous TFs could maintain their function despite a significant sequence divergence might have been overestimated (Hsia and McGinnis, 2003). Both changes in the TF expression (upstream regulation) and changes in its coding sequence can explain the evolution of transcription factor function and thus play an important role in the evolution of regulatory pathways (Hsia and McGinnis, 2003).

Recently, it was suggested that evolution with respect to expression levels is neutral. Khaitovich *et al*. (2004) observed similar divergence of gene expression levels for real and pseudogenes. However, Jordan *et al*. (2005) recently reported on a study including tissue specific expression levels in rat, mouse, and human. They suggested that while there may be a degree of neutrality in genes that are less important for an organ, selective constraints prevail on gene expression divergence. While clocklike rates of neutral evolution were found for sequence divergence of genes, the divergence of profiles with respect to tissue specificity across species suggested that selective constraints dominate.

8. Conclusions

Over the last years, the availability of genomics, proteomics, and transcriptomics data have significantly enhanced our understanding of evolution of complex networks and, at the same time, enabled us to transfer knowledge from better studied model organisms (such as *E. coli* and yeast) to those for which fewer data are available but, for example, a genome has been analyzed by low shot-gun coverage. In essence, the following picture, which will undoubtedly undergo revisions in the near future, is beginning to emerge:

- Most ancestral to genetic networks as we observe them today were probably a small group of DNA-binding domains that, while conserving their structure (fold), diverged into a large variety of TFs. Ancestral proteins are widely believed to have been single domain proteins.
- More recently, most proteins, among them probably TFs, underwent many cycles of domain rearrangements (Bornberg-Bauer *et al*., 2005). Additional dimerization and sensoring domains were added and often lost again.
- More ancestral regulatory genes are, in the light of today's situation, often retained and have maintained a key role, for example, in regulating function-specific modules. They evolve further, preferentially by series of single-gene duplications, thus generating networks of regulatory genes that arrange into these modules. They can be colocalized and systematically build up units of higher complexity. These events can be quite recent and lineage specific as we have learned from the uneven distribution of some TF families.
- A growing number of findings suggests that structurally similar or even identical motifs can arise repeatedly and thus represent a simple level of convergent evolution.
- More complex modules, which may also have preferentially arisen by series of single-gene duplications, gave rise to similar topologies. They are, typically, collections of regulatory genes with a tightly linked function and correlated expression that are well controlled by the descendants of the ancestral gene.
- Large-scale duplications may have been important in generating specific network structures as we see them today and increase complexity but probably they were not instrumental for establishing the networks.
- The evolution of promoter regions is less understood, although of great importance. Genotypic changes at this level are probably among the main reasons why, in spite of minor interorganismic differences at the level of proteins, major changes in the topologies of genetic networks during development induce a wide morphological difference and diversity in todays creatures.
- While there is no evidence for selection on topological motifs and modules, expression studies suggest that selection of expression levels per se does take place.

In summary and, although intuitively difficult to grasp, the evolutionary mechanisms in generating diverse networks with dramatic phenotypic changes are taken from the well-known standard repertoire of evolutionary operators: gene duplication, redundancy, functionalization, neutral and selective evolution, gene loss,

and modular rearrangements. Taken together, these insights are "Taking the mystery out of biological networks" (Aloy and Russell, 2004). So, although we are nowhere close to rationally constructing or predicting the complex behavior of gene-regulatory networks in the cell, we are beginning to understand their evolutionary dynamics.

Short Specialist Review

Phylogenomic approaches to bacterial phylogeny

Vincent Daubin

University of Arizona, Tucson, AZ, USA

Université Claude-Bernard Lyon 1, Villeurbanne, France

1. Introduction

Because phylogeneticists are in a constant quest for more phylogenetic characters, the approaches aimed at building trees using multiple genes and complete genome sequences have become quite popular. Genome sequences can be used in different ways to generate pertinent phylogenetic information. The most widely applied approach consists in concatenating several sequence alignments in order to increase the statistical power of phylogenetic methods (*see* Article 42, **Reconstructing vertebrate phylogenetic trees**, Volume 7). Other characters such as the presence of genes, gene families, or protein domains in genomes have also been used. While the benefits of such methods are evident, their application supposes that certain hypotheses are respected. In bacteria, for instance, it is quite certain that the first of these hypotheses – that genes follow a pattern of strict vertical inheritance and thus provide reliable markers of species phylogeny – has been repeatedly violated. Intertwined with limitations due to such biological phenomenon are a number of methodological and theoretical pitfalls that need to be identified. In this review, I will discuss the importance of these limitations with regard to recent literature and the applicability of a phylogenomic approach to bacterial history. Because an unrooted tree of bacteria has very little to say about their history, I will mostly discuss attempts to reconstruct the tree of life.

2. The organismal phylogeny: are we chasing after Chimeras?

The first tree of life based on molecular data has been proposed by Woese *et al*. (1985) on the basis of a single gene, the RNA of the small subunit of the ribosome (SSU rRNA) (*see* Article 40, **The domains of life and their evolutionary implications**, Volume 7). This gene has the advantage of being ubiquitous and extremely well conserved in cellular organisms. Although the whole classification of bacteria is based on this single gene, its use as a unique reference has been questioned. Moreover, the SSU rRNA phylogeny defines a number of strongly

cohesive bacterial groups, but the relationships among these groups are poorly supported. The only robust information about the ancient history of bacteria provided by the SSU rRNA phylogeny is the basal position of the hyperthermophilic bacteria *Aquifex* and *Thermotoga*, but this result has been recently challenged (Brochier and Philippe, 2002). Therefore, there is a need to investigate the history of bacteria (and the reliability of the current classification) using independent information.

Bacteria, and more generally prokaryotes, are certainly very special organisms when it comes to phylogenetics. Lateral gene transfer (LGT) is frequent in bacteria, and its impact on phylogenetic inference can be dramatic. The abundance of LGT is supported by two main observations: first, incongruence is frequently observed among gene phylogenies when considering genes from distantly related bacteria (Brown *et al*., 2001; Brochier *et al*., 2002; Gogarten *et al*., 2002); second, the differences in gene repertoires among bacteria are striking at every phylogenetic level, suggesting constant gene acquisitions and nonhomologous replacements (Ochman *et al*., 2000; Daubin *et al*., 2003a, b; Koonin, 2003). Traditionally, genes encoding proteins involved in intimate relationships with the cell apparatus have been considered resistant to LGT, because their sequences result from a long coevolution during which they have established precise interactions with other proteins (Jain *et al*., 1999). However, cases of LGT have been described in the heart of the ribosome (Brochier *et al*., 2000), and have affected ribosomal RNA, at least in some groups (Ueda *et al*., 1999; Schouls *et al*., 2003). Thus, it is likely that virtually every gene tree will show evidence for LGT if the species sampling considered is wide enough.

These results have led some phylogeneticists to suggest that, because of LGT, "treelike phylogenies are inadequate to represent the pattern of prokaryotic evolution at any level" (Gogarten *et al*., 2002; see also Doolittle, 1999). However, this view is reducing the organisms to their genes. In the absence of cell fusion and despite LGT, the history of cell lineages is a sequence of successive divisions, which can be appropriately described as a tree. In contrast to eukaryotes, where endosymbiosis seems to have occurred repeatedly, there is no evidence suggesting that free-living bacterial species are hybrids or chimeras. Therefore, contrary to previous claims, the abundance of LGT in bacteria simply questions genes as adequate phylogenetic markers for inferring the organismal phylogeny and not the fact that such a phylogeny has existed. Although the pervasiveness of LGT can be estimated without reference to the history of cell lineages, it is only by considering this history that we can understand the biological significance of LGT.

Although the debate has been presented as a challenge to a Darwinian treelike vision of evolution, it appears that the relevant question is not whether the tree metaphor is appropriate to represent the history of bacteria but whether the gene sequences carry pertinent information about the history of cell lineages?

A high degree of LGT is not in contradiction with the concept of organismal phylogeny, but it may forbid its reconstruction. To address this question, it is possible to systematically compare the phylogenetic information of different genes to evaluate the extent of conflict. Different approaches have been proposed to address this issue. A first method consists in comparing the topologies of orthologous gene trees to a reference tree, believed to be the species phylogeny. Such an approach

has been used by Jain *et al*. (1999) using the data from six complete prokaryotic genomes (four bacteria and two archaea). These authors found that most trees derived from orthologous genes were incongruent with the reference and interpreted this result as an evidence for continual horizontal transfers. However, the same approach applied to six complete eukaryotic genomes (three animals, two fungi, and one plant) has revealed a very similar degree of conflict between trees (Wolf *et al*., 2004). Because such a frequency of LGT can hardly be hypothesized, especially among different eukaryotic kingdoms, it appears that the test is probably inappropriate to measure reliably the extent of LGT. Other methodologies that evaluate the adequacy of alternative topologies with gene alignments using Maximum Likelihood approaches have suggested high degree of conflict (Zhaxybayeva and Gogarten, 2002), but again, these approaches may be too sensitive to phylogenetic artifacts because they only consider four genomes at a time (Daubin and Ochman, 2004). These studies have addressed the question using few anciently diverged species, and probably suffered from insufficient taxon sampling, with the result that the incongruences observed among genes could be interpreted as due to phylogenetic artifacts rather than LGT. In contrast, analysis of more closely related species (Daubin *et al*., 2003b) or using better species sampling (Lerat *et al*., 2003) have revealed remarkable congruence between orthologous gene histories. Although these studies addressed the history of a group of species rather than the entire bacterial domain, they demonstrated that sequences contain exploitable information to infer the organismal phylogeny and that given the rates at which LGT has been reported to occur (Ochman *et al*., 2000; Daubin *et al*., 2003a), orthologous genes constitute surprisingly good phylogenetic markers. However, these studies do not prejudge of the applicability of phylogenomic methods to the inference of relationships between bacterial phyla.

3. Phylogenetics in the genomic era

Several attempts to reconstruct the tree of bacteria using the data from complete genomes have been published. The different methods proposed can be classified into two groups: those using the phylogenetic signal of numerous genes to increase the statistical power of the phylogenetic methods and those defining global indexes of similarity between genomes, for instance by comparing gene content (*see* Article 49, **Chromosome phylogeny**, Volume 7).

There are two main approaches using the phylogenetic signal contained in gene sequences. It is possible to apply these methods without having complete genome sequences. The most intuitive of them is the concatenation of genes (Teichmann and Mitchison, 1999; Brown *et al*., 2001; Wolf *et al*., 2001; Brochier *et al*., 2002; Matte-Tailliez *et al*., 2002). It anticipates that large sequence alignments will increase the robustness of the phylogenetic signal and consists in concatenating all the orthologous genes available into a "super-alignment". Every concatenation approach admits a priori that individual genes may not, for a reason or another, represent the species phylogeny but may contain information that can be revealed when confronted to other genes. In conducting such an analysis, it is necessary to use a method that allows different sites of the alignment to evolve at different rates

because genes may be informative at different evolutionary scale. The principal limitation of this approach is that it requires the genes to be present in all or much of the species considered. This restriction results in the limited number of genes that can be used, especially in the case of the tree of life, with the consequence that one or a few long genes may rule over the phylogenetic signal of other genes in the "super-alignment". Such problems can have dramatic effect when genes having undergone LGT are included in the "super-alignment" (Teichmann and Mitchison, 1999; Brown *et al*., 2001). The most current practice in this case is to exclude the alignment of the genes presenting evidence for LGT, even if only one or a few species are concerned. In a study of the tree of life by Brown *et al*. (2001), as much as nine gene alignments (over 23) were excluded (because their individual trees presented the bacteria as not monophyletic), resulting in removing more than 40% of the phylogenetic information.

A possible alternative is the "supertree" method (Daubin *et al*., 2001, 2002). Here, the genes trees are combined instead of the alignments. The great advantage of this method over the concatenation approach is that it allows combining trees that share only a few species. For the inference of the tree of life, it raises the number of informative genes from two dozen to several hundreds. It also resolves the problem of the dominance of a gene over the others because each gene tree is given approximately the same weight in the analysis. The potential impact of LGT is thus reduced. The main limitation of the method is that it reduces the phylogenetic information of a gene to a single tree that is not guaranteed to be the true tree. Therefore, in contrast to the concatenation approach, there is no possibility for a weak phylogenetic signal present in several genes to be valorized by the analysis. The "supertree" approach will rather deal with conflicting information in the manner of a consensus method. Both the concatenation and the "supertree" approach have confirmed most of the evolutionary groups proposed by Woese *et al*. (1985) and have even brought some new insights into the ancient history of bacteria.

The other class of methods defines a global index of resemblance among genomes and requires having complete genome sequences. One of the first trees based on global comparison of genomes has been proposed by Snel *et al*. (1999), where the index of similarity between two genomes was defined as the ratio of the number of shared orthologs and the number of genes present in the smallest of them. It is important to note that such a method uses phylogenetic characters that are independent from a concatenation approach, which considers genes that are shared among all species. In a study of genome content, only genes that have limited phylogenetic distribution are considered as informative characters. This approach has been surprisingly successful in recovering most of the groups that had been defined on the basis of the SSU rRNA phylogeny. Numerous other approaches that instead of shared orthologs use the presence of gene families or protein domains families have been proposed (Fitz-Gibbon and House, 1999; Tekaia *et al*., 1999; Lin and Gerstein, 2000; House and Fitz-Gibbon, 2002). These characters have proved to be informative at some phylogenetic level, allowing to recover the monophyly of Bacteria, Archaea, and Eukaryotes, but generally fail to infer more precise relationships. These differences with the results from Snel *et al*. (1999), can be explained by the reduction in the number and the quality of informative characters (protein domain families may contain several gene families that themselves contain

several families of orthologs). Other authors have defined the resemblance of two genomes as a function of the BLAST scores obtained when comparing all genes from a pair of genomes (Clarke *et al*., 2002). These approaches, again, confirmed most of the groups defined by Woese.

4. Reconstructing the history of bacteria: despite or thanks to LGT?

The similarities in the trees obtained from independent phylogenomic methods have been suggested to be the result of LGT. In this view, the grouping observed in these trees would only reflect the propensity of bacterial species to exchange genes (Gogarten *et al*., 2002). Indeed, an expected consequence of LGT is the illegitimate grouping of species, both in gene trees and gene content–based phylogenies. However, such a hypothesis predicts that gene phylogenies will show conflict between each other at the narrowest phylogenetic level because the species that "seem" closely related exchange genes frequently. This prediction is clearly rejected by the analysis: genes sampled from closely related species show remarkable phylogenetic congruence, demonstrating that vertical transmission of orthologous genes is prevalent in the short term (Daubin *et al*., 2003b; Lerat *et al*., 2003). Therefore, the congruence of the results obtained from different phylogenomic approaches implies that the phylogenetic signal has also been sufficiently conserved for a phylogeny to be inferred, at least within bacterial phyla. Interestingly, genome content, if used appropriately, appears to be suitable for phylogenetic inference, indicating that the acquisition of new genes by LGT, though frequent, is not an overwhelming source of homoplasy.

Most of the difficulties in reconstructing the bacterial phylogeny reside in the deepest nodes of the tree, and particularly in the position of its root. The antiquity of bacteria is a major barrier in reconstructing their history and it is possible that most of the phylogenetic information has been erased. However, despite the growing number of complete bacterial sequenced genomes, the current sampling of their diversity in genome databases is still very limited. The availability of more genomes should increase the reliability of the approaches described here. Ultimately, the combination of phylogenomic approaches will allow documentation of the events, including vertical inheritance, LGT, and gene loss, that have shaped contemporary and ancestral genomes.

Acknowledgments

I would like to thank Emmanuelle Lerat for comments on this paper.

Short Specialist Review

Phylogenomics for studies of microbial evolution

Siv G. E. Andersson and Hans-Henrik Fuxelius
Uppsala University, Uppsala, Sweden

1. Introduction

The classification of microorganisms represents a major challenge, the basis of which has been an issue of debate for the past 100 years (Woese, 1994). Phylogenetic inference based on rRNA sequences is currently the gold standard for studies related to microbial evolution and classification. As more and more microbial genomes are added to the rapidly expanding pool of sequence data, automatic systems are being developed to meet the growing demand for large-scale phylogenetic analyses. However, the development of such tools and their application to biological problems has raised more questions than has been solved, and the debate about the extent to which microorganisms are related by vertical descent versus horizontal transmission is more heated than ever before. Here, we describe the recent development of methods and tools for phylogenomic studies and their application in microbiological research.

2. Ribosomal RNA trees

More than 100 years ago, attempts were made to construct a bacterial classification scheme, following the Linnean tradition. However, morphological and biochemical characters were found to be too simple, and the phylogenetic approach to microbial classification was explicitly abandoned in the mid-1960s. Ironically, only 10 years later, Carl Woese revolutionized biology by constructing a phylogenetic tree based on rRNA sequences, the so-called Tree of Life, which suggested that the prokaryotes (cells without a nucleus) belong to two genetically different groups, Bacteria and Archaea, each of which is equidistant from the eukaryotes (cells with a nucleus) (Woese *et al*., 1990). Since then, rRNA sequence data has been collected from thousands of organisms, and rRNA trees have modernized microbiology by providing a reference system for diagnosis, classification, and evolutionary investigations.

3. Genome annotation by sequence similarity searches

The first task in the analysis of a newly sequenced genome is to predict the location of genes and assign putative functions to the identified genes. Since experimental data is in most cases missing, the functional assignment (*annotation*) is based on sequence similarity to genes in other species with an already assigned function that was experimentally determined. The most widely used program for such sequence similarity searches is BLAST (Altschul *et al*., 1997), which is a rapid and simple method to detect closest matches in database searches.

This method is ideal for the analysis of genome sequence data from the point of view that it can easily be automated for the annotation of thousands of genes. The results may be graphically mapped onto circles that display the order of genes, with colors representing the functional categories to which the annotated genes belong. Additional circles can be added to detail the species to which a hit for any given gene was identified. Regions without similarity to genes in the databases are visualized as "holes" in the circles, as seen, for example, in the genome circle of *Francisella tularensis*, the causative agent of tularemia (Larsson *et al*., 2005). Such species-unique segments, also called genomic islands, often represent horizontally acquired DNA that putatively code for proteins involved in pathogenesis and/or environmental adaptation.

Despite the many virtues of the BLAST program, a limitation is that it does not distinguish orthologs related by vertical descent from members of large gene families that share a relationship due to gene duplication events. Within a family, all gene members share some sequence similarity. Yet, the encoded proteins may perform related but not necessarily identical tasks due to functional divergence following the gene duplication events. Hence, it is very difficult to infer functional equivalence solely on the basis of sequence similarity inferred with the aid of the BLAST program.

4. Phylogenetic methods

Phylogenetic methods differ from BLAST methods in that they were developed to provide exact measures of the internal relationships of a limited number of sequences. To this end, the sequences to be analyzed need first to be extracted from the public databases with the aid of BLAST, after which they are aligned using programs such as CLUSTALW (Thompson *et al*., 1994). The evolutionary relationships of the taxa represented by the aligned sequences can then be explored using a variety of tree reconstruction methods, such as, for example, distance-, parsimony-, maximum likelihood, and Bayesian methods. Finally, the statistical support for each cluster of taxa is estimated.

Thus, phylogenetic inference includes a series of steps; (1) manual extraction of sequence data from the databases, (2) alignment of the selected sequences, (3) editing of the alignment, (4) selection of substitution models, (5) inference of the tree topology, (6) statistical testing of the identified clusters, (7) visualization, and (8) inspection of the resulting trees. Until recently, each of these steps required manual intervention and it is only with the recent development of automatic

tools that phylogenetic methods have become a realistic alternative to the simpler sequence similarity methods used for large-scale analyses of genome sequence data.

5. Phylogenomics

The term "phylogenomics" refers to the application of phylogenetic methods to whole-genome sequence data. Automatic tools for phylogenetic inferences are of practical use in genome annotation projects and are also of great interest to explore the occurrence of horizontal gene transfer events. With the aid of such methods, sequences are extracted and aligned automatically, and trees are built and visualized in a fully automated manner. One of the first such tools was applied to the analysis of seven microbial genomes and resulted in the construction of more than 8000 individual phylogenetic trees (Sicheritz-Ponten and Andersson, 2001). An interesting observation from this early study was that although a majority of trees supported the rRNA division of bacteria and archaea, a substantial fraction of trees deviated from the expected pattern (Sicheritz-Ponten and Andersson, 2001).

6. How to describe life?

The incongruence between the many individual gene trees constructed in phylogenomic studies has been used as an argument in favor of the hypothesis that horizontal gene transfer events occur frequently in the microbial world. Indeed, mechanisms for DNA transfer are well known for decades: transformation, transduction, and conjugation all contribute to the exchange of genes within and among bacterial populations. Among genes typically encountered on transmissible plasmids are those for antibiotic resistance and environmental adaptation. Some people argue that horizontal gene transfer events occur so frequently that the tree of life is not a proper description of the relationships among microbial species. For example, the proponents of the web-of-life model argue that life should instead be represented as a web, in which microbial cells freely exchange DNA within and among populations (Doolittle, 1999).

Although phylogenomic studies are indicative of extensive gene exchange, they support the notion that the separation of Bacteria and Archaea into two separate domains is robust, that is, not distorted by horizontal gene transfer. This suggests that there is a backbone of genes with an evolutionary history that is in harmony with the "universal tree of life" (Sicheritz-Ponten and Andersson, 2001). This is also consistent with the results from comparative genome analyses, which have shown that microbial genomes consist of vertically inherited regions interspersed with horizontally acquired blocks of DNA. The sequences inside these islands are turning over much more rapidly than the remainder of the genome. This may be because most of such genes are not essential or only required under certain environmental conditions.

7. Phylogenomics – problems and pitfalls

A pertinent question that needs to be asked is whether the many gene trees obtained in phylogenomic studies accurately record the evolutionary history of the individual genes? Phylogenetic inference is based on a number of assumptions, such as, for example, that the genes are conserved to an extent that matches the studied divergences and that they are functionally equivalent so that they evolve under identical selective constraints. Ideally, the genes under investigation should also evolve at similar rates and have similar base composition patterns.

In real case studies, these assumptions are often violated, which may result in tree artifacts, that is, the obtained tree topology may not necessarily reflect the evolutionary history of the gene. Because evolution has only happened once and since we do not know the order of divergences a priori, there are few test grounds under which the assumptions and models used in phylogenetics can be tested. Such experiments would be particularly relevant for phylogenomic studies in which there are few opportunities to manually inspect the reconstructed trees.

Fortunately, there are a few biological systems that may be used to examine the accuracy of whole-genome phylogenetic methods. These include endosymbionts that have coevolved with their hosts and for which horizontal gene transfer events are expected to be rare or nonexistent. A recent examination of the incongruence of a few hundred gene trees from *Buchnera aphidicola* suggests that biased mutation pressures and enhanced substitution rates may severely distort tree topologies (Canbäck *et al*., 2004). Incorrect nodes are often supported by high bootstrap support values, which further complicates the interpretations of the phylogenomic analyses. Great care should therefore be taken before drawing conclusions from phylogenomic studies.

8. Conclusions

Phylogenomic methods offer a wonderful opportunity to perform sophisticated analyses of large sequence data sets in an automatic manner, studies that have until recently been considered unrealistic. Now that the bioinformatic methods are in place, biological expertise is required to pose interesting questions about the structure of life – and to interpret the results obtained in a meaningful manner.

Short Specialist Review

Mapping mutations on phylogenies

Rasmus Nielsen
Cornell University, Ithaca, NY, USA
Bioinformatics Centre, University of Copenhagen, Copenhagen, Denmark

1. Introduction

The role of comparative genomic data analysis is often to make inferences regarding the pattern and distribution of mutations. For example, conserved nucleotide or amino acid sites can easily be identified if the number of mutations occurring on a phylogeny can be inferred (*see* Article 41, **Phylogenetic profiling**, Volume 7). Likewise, studies aimed at detecting correlated amino acid substitutions (e.g., Shindyalov *et al*., 1994) or positively selected sites (e.g., Bush *et al*., 1999) are easily conducted if mutations can be inferred on a phylogeny. In the following, we will refer to a set of mutations inferred on a phylogeny (a character history) as a *mapping of mutations*. In an alignment of n sequences, each sequence is associated with a leaf node (terminal node) in a binary unrooted tree with $2n - 3$ branches (edges). An example of such an unrooted tree for $n = 5$ is depicted in Figure 1. For a single site (a column in the alignment), each branch in the phylogeny is associated with zero or more mutations, such that the pattern of mutations in the tree is compatible with the sequence data. In the example of Figure 1, the observed data for a single site is *GCCGT*. For the particular tree shown in Figure 1, any mapping of mutations requires a minimum of three mutations. One of the (infinitely) many possible mappings are shown in Figure 1, requiring two $C \Leftrightarrow G$ and a $G \Leftrightarrow T$ mutation. In this notation, mutations are bidirectional because the tree is unrooted. In rooted trees, the direction of the mutation can be inferred and mutations of type $i \rightarrow j$ will be distinguished from mutations of type $j \rightarrow i$.

2. Parsimony mappings

It is clear that if the true mapping of mutations on a phylogeny is known it is easy to make inferences regarding rates and patterns of substitution. Standard statistical tests can be used to determine if certain branches in the phylogeny or certain sites in the alignment have an overrepresentation of mutations. Likewise, we can test if certain types of mutations occur more frequently than other mutations or

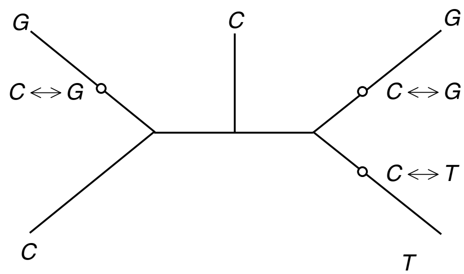

Figure 1 An example of a mutational mapping on a tree with five leaf nodes

if mutations in certain sites tend to co-occur with each other. Such methods have been used extensively in the literature, for example, for detecting selection (e.g., Fitch *et al*., 1997; Bush *et al*., 1999; Wyckoff *et al*., 2000), detecting correlated evolution (e.g., Shindyalov *et al*., 1994), or for making inferences regarding the distribution and pattern of mutations among sites (e.g., Wakeley, 1993, 1994). A real and important challenge in this regard is that the true mapping of mutations will not be known. It must instead be inferred using a statistical methodology.

The most commonly used approach for mapping mutations on a phylogeny based on a given sequence alignment, is to use the maximum parsimony principle. According to this idea, a mapping of mutation should be chosen that minimizes the total number of mutations in the tree. The mapping shown in Figure 1 is a maximum parsimony mapping because no other valid mapping exists requiring fewer mutations than three. However, another parsimony mapping would assign the two $C \Leftrightarrow G$ mutations to the branches leading to the leaf nodes associated with C. A maximum parsimony mapping is not necessarily unique.

Mutational mappings have been used in a number of exciting publications. For example, by mapping mutations on phylogenies based on sequences from the influenza hemagglutinin gene, Fitch *et al*. (1997) and Bush *et al*. (1999) were able to demonstrate that the ancestral lineages of the influenza virus, which lead to new epidemics, have particular properties with respect to the mutations that occur on them. This opened up the possibility that it might be possible to predict which of the current influenza strains may lead to the next epidemic.

Another example of the use of parsimony mappings is in the study of correlated evolution. If certain amino acid (aa) residues in a protein interact, they may be expected to evolve in a correlated fashion. There has, therefore, been considerable interest in identifying such correlated aa residues (e.g., Altschuh *et al*., 1987; Shindyalov *et al*., 1994; Pollock *et al*., 1999). In evolutionary biology, there has long been considerable interest in identifying methods for detecting correlated character evolution, of morphological as well as molecular characters (e.g., Ridley, 1983; Felsenstein, 1985; Maddison, 1990; Harvey and Pagel, 1991). Mapping of mutations are highly useful for this purpose because they may help identify pairs of sites (characters) in which mutations (character changes) tend to co-occur in the same lineages of a phylogeny (e.g., Ridley, 1983; Maddison, 1990; Pagel, 1994; Shindyalov *et al*., 1994).

3. Probabilistic approaches

Although parsimony mapping has been a very useful tool for many years in the study of molecular evolution, it is, from a statistical perspective, not ideal. The most likely mapping may in many cases not be a parsimony mapping, and the use of a methodology that always tends to choose the fewest number of mutations, may in some cases bias the results of a study (e.g., Nielsen, 2002). Even more importantly, the use of parsimony mappings usually does not take into account the uncertainty associated with the mappings, that is, the inferred mutations are treated as real data even though they are associated with some statistical uncertainty. Many of these problems can be circumvented by instead focusing on methods that implicitly sum over all possible mappings. Among such methods are the, now classical, likelihood methods for making inferences about molecular evolution (e.g., Felsenstein, 1981; Yang, 1994). In these methods, the evolution of a nucleotide site or an amino acid site is described as a continuous time Markov chain model. The Markov model is defined by the state space, $\Phi = \{A, C, T, G\}$, and an infinitesimal generator (rate matrix) $\mathbf{Q} = \{q_{ij}\}$, $i,\ j \in \Phi$, where q_{ij} is defined as $q_{ij} = -\sum_{k:k \neq i} q_{ik}$ for $i = j$, and the stationary distribution of the process is given by $\pi = (\pi_A, \pi_C, \pi_T, \pi_G)$. Notice that $-q_{ij}$ is the rate of substitution out of state i. Inferences are made by superimposing this Markov process along the branches of the tree. By multiplying transition probabilities, from the root, along the branches of the tree, summing over all possible unknown ancestral states in the internal nodes, the likelihood function under any Markov model of evolution can be calculated. When transition probabilities of the Markov chain are calculated, this calculation implicitly sums over all possible mapping of mutations. However, in many cases it may still be desirable to focus on mapping of mutations, for example, for exploratory data analysis or for analysis of models or hypotheses that are not computationally tractable using methods that analytically sums over all possible mappings. In such cases, it may, from a statistical standpoint, be more attractive to focus on the probability distribution of mappings of mutations instead of a single parsimony mapping.

Given a fixed phylogeny (topology and branch lengths) and a specified Markov model of evolution, the probability of observing a particular mapping of mutations M given the sequence data D, can easily be calculated (Nielsen, 2001, 2002). For a single site, D consists of a sequence of nucleotides of lengths n and M is a set of mutations in which each mutation is identified with respect to type (e.g., $C \Leftrightarrow G$), branch and time (position on the branch). The conditional probability density of M can be calculated as

$$p(M|D) = \frac{p(M, D)}{p(D)} \tag{1}$$

where $p(D)$ is the usual likelihood function, although the parameters have been suppressed in the notation here, and it can be calculated using standard methods (e.g., Felsenstein, 1981). $p(M, D)$ can be calculated by noting that if the current state of the chain is i, the waiting time to the next mutation is exponentially distributed with parameter $-q_{\text{ii}}$, and the probability that the mutation is of type

$i \to j$, given that a mutation happens, is $-q_{\mathrm{ij}}/q_{\mathrm{ii}}$. For time-reversible models, $p(M, D)$ can then be calculated by placing the root of the tree arbitrarily in any node of the tree and multiplying the appropriate density functions and probabilities along the branches of the tree starting in the root node. For example, consider the tree and mapping of mutations in Figure 2. By multiplying densities and probabilities along the edges of the tree from the root, we find for this particular tree and mapping of mutations

$$\begin{aligned}\Pr(M, D) &= \pi_G \left(\mathrm{e}^{qGG^{t_1}}\right)\left(\mathrm{e}^{qGG^{t_2}}\right)\left(\frac{qGC}{-qGG}\right)\left(-qGG\mathrm{e}^{qGG^{t_3}}\right)\left(\mathrm{e}^{qCC^{t_{42}}}\right)\\ &= \pi_{GqGC}\mathrm{e}^{qGG}(t_1 + t_2 + t_3) + qCC^{t_{42}} \qquad (2)\end{aligned}$$

In general, the probability density of a particular mapping is given by

$$p(M, D) = \pi_a \mathrm{e}^{\sum_{i \in \Phi} q_{ii} T_i} \prod_{(j,k):j \neq k} q_{jk}^{x_{jk}} \qquad (3)$$

where a is the ancestral nucleotide in the root imposed by M, x_{jk} is the number of mutations in the rooted tree of type $j \to k$, and T_{i} is total time in tree in which the Markov process is in state i. Under models of evolution where the embedded point process is a Poisson process, that is, $q_{ii} = q_{jj}$, for all i and j, Pr(M,D) reduces to

$$p(M, D) = \pi_a \mathrm{e}^{q_{aa} T} \prod_{(j,k):j \neq k} q_{jk}^{x_{jk}} \qquad (4)$$

where T is the total tree length, that is, $T = \sum_{i \in \Phi} T_i$. Notice that in these models, the position of a mutation along a branch does not influence the probability of the mapping.

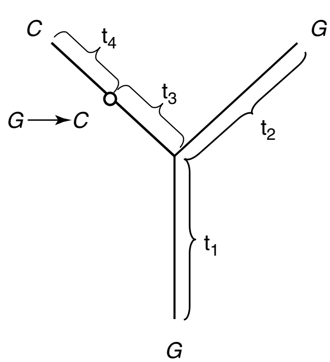

Figure 2 A mutational mapping on a tree with three leaf nodes and times of mutations indicated on the tree

4. A numerical example

As an example, consider the phylogeny in Figure 2 and assume $t_1 = t_2 = t_3 + t_4 = 1$. For simplicity of the example, further assume a Jukes and Cantor (1969) model of evolution, in which $q_{ij} = 1/3$ for all $i \neq j$ and $\pi_i = 1/4$ for all i. Then, using standard methods (e.g., Felsenstein, 1981) we find that the probability of the observed data (C, G, G) is $p(D) = 0.0161$. Likewise, we can calculate the joint probability density of the depicted mapping and the data as $p(M, D) = (1/4)e^{-1\times 3}(1/3) = 0.0041$. So the probability density associated with the mapping depicted in Figure 2 is $0.0041/0.0161 = 0.2571$, for any particular value of t_3. Integrating over all possible values of t_3, we find that the probability that a mapping with a single $G \Leftrightarrow C$ mutation is the correct mapping is 0.2571. Had we instead assumed $t_1 = t_2 = t_3 + t_4 = 0.1$, we would have found this probability to be 0.9290. The probability of different mappings depends on the branch lengths, and with sufficiently long branches the probability that any of the parsimony mappings is the right mapping can become very small. Nielsen (2002) gave an example in which a nonparsimonious mapping was more than 1000 as likely to be the right mapping as the parsimony mapping.

This basic approach for assigning probabilities to particular mappings also allows simulation of mappings of mutations and statistical inferences based on mapping of mutations. An efficient simulation algorithm for simulating mutational mappings from $p(M, D)$ was described in Nielsen (2002). In brief, using Felsenstein's (1981) pruning algorithm, the conditional probabilities of the nucleotide states in all nodes are calculated. Starting from the root, the ancestral states at each node are then simulated on the basis of these probabilities. Finally, given the ancestral state at each node, the mutational path along an edge can easily be simulated from the correct distribution using standard Markov chain theory.

In the probabilistic approach, inferences regarding the pattern of substitutions are done by focusing on a distribution of mappings instead of a single estimated mapping. In this way, statistical uncertainty in the mapping can be taken into account. By simulating mappings of mutations from the posterior, $p(M|D)$, estimates of parameters are obtained, with associated measures of statistical uncertainty. Hypothesis testing can be done by comparing the inferred distribution of mappings to the distributions expected under a given null hypothesis. Uncertainty in the parameters of the model of molecular evolution, and uncertainty regarding tree topology and branch lengths, can also be taken into account by combining the mapping of mutations approach with the now classical Bayesian approaches in phylogenetics. These concepts will be illustrated in the following sections using an application developed by Huelsenbeck *et al*. (2003) for detecting correlated character evolution.

5. Application to the detection of correlated evolution

Huelsenbeck *et al*. (2003) analyzed molecular data and the evolution of flower morphology and self-incompatibility in the family Pontederiaceae (Kohn *et al*., 1996; Graham *et al*., 1998). Although this example involves nonmolecular data,

the application of the method would work similarly for molecular data. The data consisted of *rbcL* and *ndhF* genes and data on flower morphology and self-incompatibility versus self-compatibility for each of 25 species. To distinguish the molecular from the nonmolecular data, we will use the notation D_{M} for the molecular data and D_{N} for the nonmolecular data. The major biological question investigated was to which degree the flower morphology and self-compatibility/incompatibility tend to coevolve along the branches of a phylogeny (Kohn *et al*., 1996). In particular, it was of interest to examine if self-incompatible species tend to have tristylous flowers.

To take into account uncertainty regarding tree branch length and topology, Huelsenbeck *et al*. first estimated (sampled from) the posterior distribution of trees (T) based on chloroplast *rbcL* and *ndhF* genes using the Markov Chain Monte Carlo (MCMC) algorithm implemented in MrBayes (Huelsenbeck and Ronquist, 2001). For details regarding models of molecular evolution and MCMC parameters, please see Huelsenbeck *et al*., 2003. This analysis generated a sample of k (= 8000) trees sampled from the posterior distribution, $p(T|D_M)$, that is, the distribution of trees given the molecular data. For each tree, mappings of character changes of the nonmolecular characters were simulated from the posterior distribution, $p(M_i|T_i, D_{NM})$, $i = 1, 2, \ldots, k$. This was done under a Markov model of evolution applicable to nonmolecular characters (Lewis, 2001). These mappings represented samples from $p(M|D_{NM}, D_M)$, and more than one mapping of character histories could have been sampled from each simulated tree. For each of these character mappings, a test statistic ($S^{(i)}$) was calculated. In this case, the degree of correlated evolution between the two characters was of interest. Given character mappings of two characters, the amount of time two character states are co-occurring on the tree can be directly observed. Likewise, the time the two characters states are expected to co-occur can be calculated under the hypothesis of independence in the evolution of the two characters. The test statistic was then defined as the difference between the expected and the observed proportion of times the two character states co-occur on the phylogeny. Finally, the average value of the statistic was calculated, $S = \sum_{i=1}^{k} S^{(i)}$. This procedure is illustrated in Figure 3(a).

To determine the significance of this test statistic, new data sets of the nonmolecular characters are simulated under the posterior distribution of trees (and other parameters). This was done by first simulating a set of trees from $p(T|D_M)$ and then simulating a set of new nonmolecular data sets on these trees. For each of the new simulated data sets, the previous procedure for calculating S was applied. This was again done by sampling from the posterior distribution of trees given the molecular data. This procedure is illustrated in Figure 3(b).

The results of this procedure on the Pontederiaceae data are shown in Figure 4. Because the observed value of S lies to the right of the simulated values of S, we reject the null hypothesis of independence in the evolution of the two characters and interpret this as evidence that the two characters evolve correlated.

This procedure has several advantages over previous procedures for detecting correlated evolution. Most importantly, it takes into account uncertainty both in the phylogeny and in the assignment of character mappings to the phylogeny. The exact

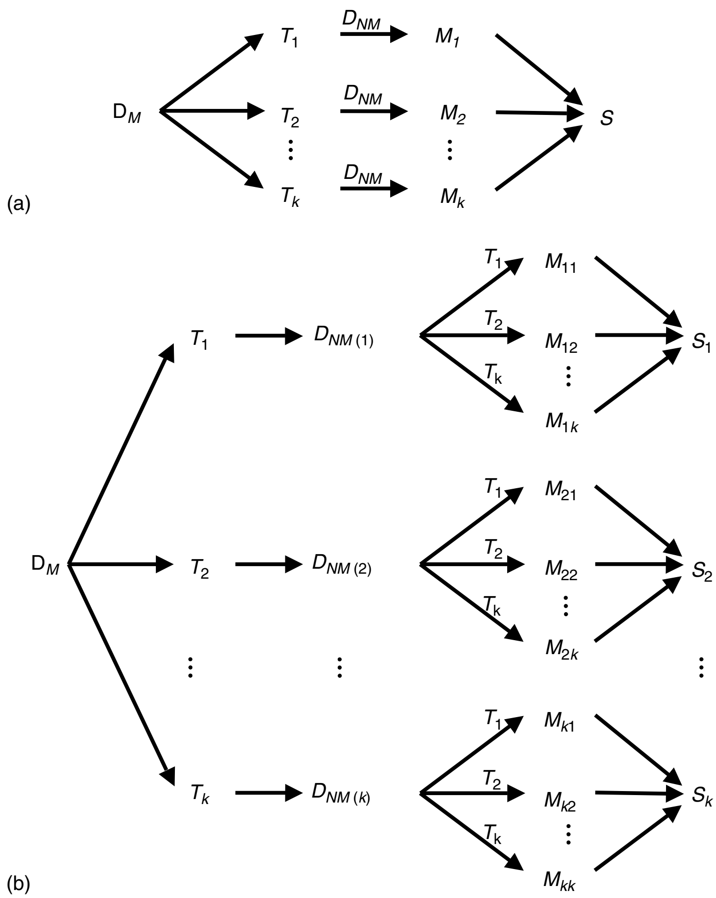

Figure 3 The procedure used to (a) calculate the test statistic and to (b) approximate its posterior predictive distribution. In (a), a sample of trees is generated from the posterior distribution given the molecular data. For each tree, a mapping of character histories are simulated from the distribution of mappings given the tree and the nonmolecular data and the test is then calculated for each mapping and averaged over mappings. (b) A similar procedure is used to generate the predictive distribution, but here the test statistic is calculated from each of k data sets of nonmolecular simulated under the posterior distribution of trees (and other parameters), under the assumption of independence between the two characters

same procedure could be applied to molecular data, replacing the nonmolecular character data with nucleotide or amino acid characters.

6. Conclusions

Mutational (character) mappings have been of tremendous importance in evolutionary biology. New probabilistic approaches can incorporate uncertainty regarding the mutational mappings into the existing approaches for analyzing data on the basis of character mappings. The new approaches are attractive because they can incorporate statistical uncertainty, but they have the disadvantage of relying on simulation,

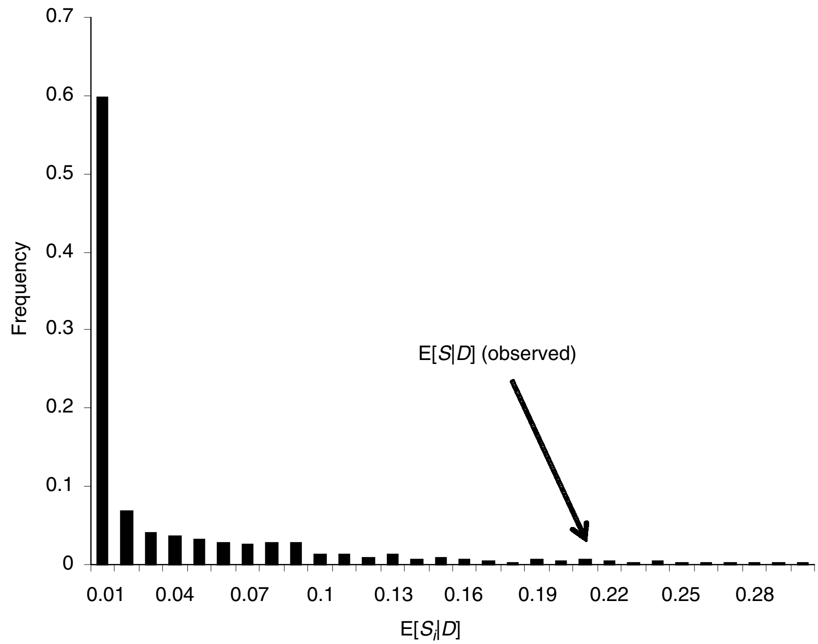

Figure 4 The simulated distribution and observed value of $E[S|D]$. $E[S|D]$ is the expected value of the correlation statistic S, where the expectation is taken with respect to the posterior distribution of mutational mappings. The simulated distribution is obtained by simulating data sets under the posterior predictive distribution

and therefore are less easy to implement and more computationally demanding than simpler methods. The parsimony-based approaches are implemented in many available computer programs including the Maclade package (Maddison and Maddison, 2000) and the Mesquite package (Maddison and Maddison, 2004), both of which offer convenient graphical user interfaces. Two computer programs are distributed that allow inferences regarding mutational mappings based on the described probabilistic approaches: Mutonphyl (Nielsen and Todd, 2004) with an interface by Nuin and Golding 2005), and SIMMAP (Bollback, 2005). The latter program has a graphic user interface that allows the user to explore distributions of mutational mappings on trees.

With the availability of new methods for mapping mutations that can take statistical uncertainty into account, mutational mappings are likely to keep their importance as one of the main inferential tools in the evolutionary analysis of molecular data.

Short Specialist Review

Phylogenetic analysis of BLAST results

Fiona S. L. Brinkman
Simon Fraser University, Burnaby, BC, Canada

BLAST (Basic Local Alignment Search Theorem; Altschul *et al*., 1990; Altschul *et al*., 1997) is the most widely used bioinformatics application developed to date (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7). It has been used extensively by both large genome projects and individual researchers alike to perform rapid heuristic identification of regions of sequences in a database that are similar to a user-provided query sequence. Its speed, ability to identify short regions of similarity (rather than global alignment of full length sequences), and free distribution have played a large role in its popularity. However, research literature is fraught with examples of ways in which BLAST analyses may be misused or misinterpreted (Peri *et al*., 2001; Pertsemlidis and Fondon, 2001; Ponting, 2001).

As with most bioinformatic analyses, BLAST uses evolutionary theory as the basis for its main assumptions. Therefore, an understanding of evolutionary theory is critical to the appropriate interpretation, and further analysis, of its results. Results should be interpreted in an evolutionary context, to fit with the assumptions being made about sequence divergence over time. Therefore, subsequent phylogenetic analysis of a BLAST result is frequently a good complement to a BLAST-based analysis. Phylogenetic analysis essentially allows one to more accurately view the relationship between sequences provided by a "one-dimensional" BLAST result. A BLAST result is essentially a unidirectional catalog of how similar a sequence is to a list of other sequences, while phylogenetic analysis, which presents results in a tree-based format, allows one to compare the degree of relationship between all sequences in the set. The "two-dimensional" view of a phylogenetic analysis can be helpful in, for example, identifying whether there are subsets of sequences in a BLAST output that could be grouped as a family. BLAST alone, for example, cannot identify whether three sequences found to be equally similar to a sequence are (Option 1:) actually all highly related to each other, or are (Option 2:) quite divergent from each other (but still equally related to the query sequence). Such information provided by phylogenetic analysis is critical when inferring function based on sequence similarity.

It has also been well documented that "the closest BLAST hit is not often the nearest neighbour" (Koski and Golding, 2001). That is, the sequence that is listed

first in a BLAST output as being similar to a query sequence is not necessarily the most similar sequence according to a phylogenetic analysis. Knowing how to handle such issues and appreciating the need to perform robust evolutionary analyses after a BLAST analysis is an important component of high-caliber bioinformatics research.

In addition to the accurate identification of the true "top hit" (most similar sequence to your query) and delineation of gene families, phylogenetic analysis is also useful for the functional assignment of orthologs and paralogs. Orthologs, representing the genes that diverged because of speciation, tend to share a more similar function (at some level) versus paralogs that have diverged because of a gene duplication event (for an overview, see Brinkman, 2004). While this issue is still being actively studied, it only makes sense that paralogs would diverge in function to some degree, since after a gene duplication event, selection for new traits in a duplicate gene may occur with less risk of the changes being deleterious, since there is another duplicate gene still performing the same function. Taken another way, there may be more selection for a paralog that has diverged in function and supplies a new, useful function versus one that stays the same, and so, again, paralogs may tend to diverge more in function versus orthologs. Of course, the specific divergence in function that may occur, and degree of divergence, can vary greatly for paralogs, and so this is a complex issue. Regardless, it has been found useful to differentiate such paralogous genes from orthologs because of their differing potential to diverge in function and because ortholog comparisons also facilitate more accurate cross-species comparisons. However, a simple BLAST analysis does not provide a clear indication of potential orthologs and paralogs. Phylogenetic analysis of BLAST results, coupled with a comparison of associated organismal phylogenetic relationships, can help reveal which genes are the likely orthologs and paralogs and aid both gene function assignment and analysis of the evolutionary history of the genes involved.

Performing phylogenetic analyses of BLAST results has become easier, now that semiautomated, Web-based methods have been developed that facilitate the creation of rough phylogenetic views of the data with a few clicks. PhyloBLAST (Brinkman *et al*., 2001) and WebPHYLIP (Lim and Zhang, 1999) provide user-friendly implementations of PHYLIP (Felsenstein, 1995) for downstream phylogenetic analysis. PhyloBLAST permits one to click on entries in a BLAST analysis (BLASTp only) and then perform an automated ClustalW multiple sequence alignment followed by phylogenetic analysis using a selection of programs from the PHYLIP package. WebPHYLIP is another Web-based implementation of the PHYLIP package, and there are many more similar resources available through an extensive collection of phylogenetic software listed with the PHYLIP website (**http://evolution.genetics.washington.edu/phylip/software.html**). Implementations focusing more on ortholog identification have also been initiated (**http://www.bork.embl-heidelberg.de/Blast2e/**; Yuan *et al*., 1998); however, often, ortholog identification is performed using programs unlinked to BLAST analysis. In general, there is still a lack of software available to facilitate rapid phylogenetic analysis of a BLAST result, or similar database search results (FASTA etc.).

Though programs such as PhyloBLAST can be useful for initial analysis, it must be emphasized that phylogenetic analysis must often be customized for a given experiment or research question (Brinkman, 2004; Brinkman and Leipe, 2001). While the above tools can be useful for giving a general representation of similarities between sequences, often, more customized analyses must be performed to attempt to answer a particular research question. For example, a query protein may be similar to a set of proteins according to a BLAST analysis, and subsequent PhyloBLAST analysis indicates that a subset of the sequences reflect a possible gene family that contains a mixture of putative orthologs and paralogs, relative to the query sequence. However, you may need to perform further phylogenetic analyses of subsets of these sequences, perhaps using a relevant domain of the protein only, and using other phylogenetic methods (i.e., maximum likelihood) and model tests to more accurately identify the set of sequences that may belong to the given gene family. To identify orthologs, this analysis would also need to be compared to a phylogenetic tree of the relevant organisms to compare divergence of the proteins with the species divergence. Finally, one may wish to examine particular indels (insertions and deletions) or other specific changes in the sequences in more detail and compare them to the phylogenetic analysis to identify functionally important indels/sequences and deduce how they may have evolved. Models of evolution may need to be changed to suit the data (reviewed in Brinkman and Leipe, 2001).

The benefits of phylogenetic analysis are relevant not only for further analysis of a BLAST output but also for similar database searches performed using other algorithms. Such downstream analysis of database search results is becoming increasingly important as sequence databases increase in both size and complexity. Now it is becoming common for a BLAST output to contain many copies of similar/redundant sequences. Databases searched also contain strong biases in terms of what sequences are available from what organisms (for example, there is a dearth of protozoan genomic sequence versus animal sequences). Such biases can be more easily viewed in some cases through phylogenetic analysis. However, while sequence databases are growing in size at significant rates, we are only beginning to understand the true diversity of life that exists on earth. Environmental genomic sampling, and other studies of diversity, are confirming that we have only scratched the surface of the true complexity and variety of sequences that exist in nature (Tyson *et al*., 2004; Venter *et al*., 2004). Therefore, rapid database searches, coupled with linked phylogenetic analysis and additional evolutionary analysis, will become increasingly necessary to help us grapple with the continually increasing onslaught of sequence data.

Short Specialist Review

Connecting genes by comparative genomics

Itai Yanai
Weizmann Institute of Science, Rehovot, Israel

A result of deep importance to modern molecular genetics is the observation that most biological functions are carried out by the products of multiple genes and that most genes are associated with multiple functions (Hartwell *et al*., 1999). Unraveling the functional relationships among genes thus provides a promising route to the molecular understanding of biological functions.

Examples of tight functional relationships among genes are ubiquitous. Metabolic pathways are composed of multiple gene products each corresponding to a step along the pathway. Genes of the same metabolic pathway or signaling cascade can be said to be functionally linked. Importantly, there is frequent cross-talk among the pathways, such that a gene may subserve multiple pathways: human gene GPI, glucose phosphate isomerase, is found in glycolysis, pentose phosphate, and starch and sucrose pathways. To complicate matters further, complexes of several gene products, each of which can also have membership in multiple other types of such complexes (Gavin *et al*., 2002), may actually accomplish a single metabolic step. Besides pathways, cohorts of genes regularly form functional systems such as the oxidative phosphorylation system and the flagellum. These systems are intricately structured complexes and here also we find that members of one system are actually modular and can be used in the context of multiple functional systems as in the type III secretion system and the flagellum (Gophna *et al*., 2003).

Ideally, all such interactions would be identified by experiments testing for all possible interactions among the genes. Indeed, high-throughput methods – such as yeast two-hybrid (Ito *et al*., 2001; Uetz *et al*., 2000) and tandem-affinity purification (TAP) coupled with mass spectrometry (Gavin *et al*., 2002) – are extremely useful in identifying functional links on a large scale. However, as high-throughput as these methods may be, they cannot be truly complete. Since there are on the order of N^2 possible interactions, where N is the number of genes in a genome, it is not feasible to actually test all interactions. Moreover, these methods exhibit high false-positive rates, are highly work-intensive, and to date they mostly have been used to identify protein–protein physical interactions, a subset of the more general type of functional relationships described above.

An alternative complementary approach to the brute force experiments is not unlike the one applied to comparative anatomy in the nineteenth century. In 1843,

Sir Richard Owen, the Superintendent of the British Museum, compared the skeletons of the various classes of vertebrates – fish, reptiles, birds, and mammals. From his comparisons, Owen boldly concluded that vertebrates have a common structural plan he called an “archetype”. Owen introduced the term *homology* to mean “the same organ in different animals under every variety of form and function” (1843). Thus, human fingers are homologous to bird fingers. While originally interpreting similarities as evidence of a creator’s “archetypes”, with Darwin’s introduction of evolutionary theory, homology took on a new significance. In light of evolution, homology is interpreted as similarity due to common ancestry. By comparing increasingly distant organisms, it is thus possible to trace the order of appearances of anatomical features. We find that an understanding of the historical narrative of a biological phenomenon can be of tremendous insight toward its functioning. Essentially, the relationships among a skeleton’s bones are revealed by exploiting the common ancestry of extant organisms through a comparison of the disposition of their homologies.

Relationships among a genome’s genes may similarly be revealed by analyses of their disposition in other genomes. As expected, the operational unit of comparison in such an approach is a specific kind of homology called *orthology*, most easily defined as “the same gene in different genomes”. More exactly, an inference of orthology between two genes signifies a relationship of speciation. We infer that the two genes stem from one precursor gene that was present in the most recent common ancestor before the speciation event that dispersed the two lineages.

The ability to identify orthologous relationships proved to be of revolutionary importance to genetics. The reason is that an orthologous relationship provides a strong hint toward functional conservation. Although the length of time since divergence is a correlating factor, the notion that orthologs generally maintain the same function has found wide-range experimental support. Thus, orthology is the great simplifying notion of genetics; it offers the hope that each gene in every organism will not need to be studied separately to be understood. The knowledge that one has acquired by hard work in one organism can thus be transferred to its ortholog in another organism. For example, frog histones need not be thoroughly studied because their structure and function in yeast has already been worked out in detail and the general mechanisms can be transferred. An important caveat, however, is that orthologous genes often evolve to take on vastly different functions. Nonetheless, the delineation of orthologous gene families is of such fundamental importance that it should be considered the first law of functional genomics.

Working with orthologous families of genes allows for the reformulation of the goal of identifying gene relationships. Instead of seeking to link individual genes, it is most efficient to link orthologous families. Three methods have been proposed to detect relationships among families based upon complete genomes.

The phylogenetic distribution of the members of an ortholog family is informative. A given gene family may be, for example, specific to bacteria, scattered across the microbes, or present in all organisms examined. Consider that with 100 genomic sequences, there are 2^{100} (on the order of 10^{30}) possible distributions. Specific enough to be informative, a family’s phylogenetic distribution may be taken as its fingerprint. An ortholog’s phylogenetic distribution – or phylogenetic profile – however is often not unique to it alone. In cases where another family’s profile is

identical, or comparable, it may be a lucky incidence of no biological importance or it may actually serve as a hint of a relationship between the two families.

Correlated presences and absences in the same genomes of members of a pair of ortholog families may be explained by a functional link. In other words, if the pair of genes is required for a certain function, a genome would not be expected to have only one of them. Thus, tightly coupled genes would indeed be expected to have identical profiles of occurrences (Date and Marcotte, 2003; Huynen and Bork, 1998; Pellegrini *et al*., 1999; Tatusov *et al*., 1997; Wu *et al*., 2003). The bacterial flagellum is a good example of a functional system with conserved phylogenetic profiles (Pellegrini *et al*., 1999). The principle of phylogenetic profiling has been used to identify novel pathways (Date and Marcotte, 2003).

The physical proximity of a pair of genes along the chromosome may also be of functional importance. Chromosomal proximity of genes may be maintained by selection due to a shared mechanism of expression such as operons, or perhaps, as is common in Bacteria and Archaea, because their proximity offers a better survival rate for horizontal transfer of the paired genes (Lawrence, 1999). In both instances, a functional link is appropriate. On the other hand, proximity between two genes may be of no biological importance. Adopting a comparative genomic approach, these two instances may be distinguished. It has been shown that the number of genomes in which proximity was found is correlated to the accuracy of the functional relationship prediction (Yanai *et al*., 2002). Thus, for a given pair of ortholog families, we might examine the relative proximity of the pair across genomes (Overbeek *et al*., 1999). If in a certain number of genomes the genes are proximate, we consider the two gene families linked. Interestingly, the families may be linked even if the proximities are not held in all of the genomes and, consequently, a pair of genes in one genome may be said to be linked by chromosomal proximity even if they are not actually proximate (Yanai *et al*., 2002).

Unfortunately, functional links by chromosomal proximity seem to hold only for Bacteria and Archaea examined thus far. This may be due to the fact that operon organization is most significantly a phenomenon that is limited to these kingdoms. Eukaryotic genomes tend to be less streamlined, and thus chromosomal organization may be dominated by different evolutionary forces. Regardless of this limitation, the general applicability to Bacteria and Archaea is very useful.

A third type of functional link takes advantage of an extreme case of chromosomal proximity. It has been observed that two genes that are distinct in one organism may be found as one contiguous fusion gene in another organism (Enright *et al*., 1999; Marcotte *et al*., 1999). A fusion gene generally unites genes of the same metabolic pathway or protein complex. Thus, even if nothing is known about the two genes, a functional link based upon a fusion elsewhere could be inferred on the basis of the fusion event in one (or more) of the genomes. Indeed, it has been statistically shown that fusion links tend to pair up genes of the same broad functional category (Yanai *et al*., 2001).

The major difficulty with the fusion method is that it often appears to be a special case of a general mechanism of modular genes. Most human genes, as well as those of many other genomes, are composed of multiple domains – independent structures serving as evolutionary conserved building blocks (Ponting and Russell,

2002). Since domains, such as SH2 domains for example, appear in many different kinds of genes, there is no reason to suppose a direct functional link between the domain partners. Thus, the specificity of the fusion method can be increased if fusion links are constrained to only those domains that do not appear to be promiscuous (Marcotte *et al*., 1999).

A major confounding phenomenon of these three methods involves the issue of gene duplication. Very frequently, a gene has multiple orthologs in another genome, signifying that the original gene underwent duplication since speciation (Jordan *et al*., 2001). The question of how gene function evolves following a duplication event is, in fact, one of the most interesting open questions in the genomics field today. Since functional conservation within an orthologous family is the first assumption in all the methods, the applicability of the three genomic context methods may be called into question when gene duplications have occurred across the lineages.

How applicable are phylogenetic profiling, chromosomal proximity, and gene fusion, to a genome's genes? On average, functional links in microbial genomes contain an average of 57% of an organism's complete genetic complement (Yanai and DeLisi, 2002). Interestingly, there is very little overlap in terms of links generated by the methods but considerable overlap in the genes involved in the links (Yanai and DeLisi, 2002). Thus, the links are largely additive to form networks of interactions. The links uncover substantial portions of known pathways, and suggest the function of previously unannotated genes.

The three comparative genomics methods described here apply evolutionary theory to unravel the functional organization of genomes. Comparative genomics can essentially be seen as a decent substitute for a time machine. While ancestral states of an organism would only be available to us with the use of a time machine, comparing extant genomes leads to inferences of these very states. As in other realms, knowledge of the past makes way for understanding the present.

Chromosome phylogeny

Guillaume Bourque
Genome Institute of Singapore, Singapore

1. Introduction

Impressive sequencing and comparative mapping endeavors have made available detailed whole-genome sequences and maps (Lander *et al*., 2001; Venter *et al*., 2001; Waterson *et al*., 2002). One of the stated goals of these projects is to better our understanding of organismal biology through comparative analyses (O'Brien *et al*., 1999). The rationale is that insights into the dynamics of evolution can help ascertain the underlying adaptive biochemical and physiological responses. Comparisons can be at the raw sequence level, where the focus is typically on the analysis of individual genes, or at the coarse genomic level where the focus is on large-scale rearrangement events (*see* Article 42, **Reconstructing vertebrate phylogenetic trees**, Volume 7 and Article 44, **Phylogenomic approaches to bacterial phylogeny**, Volume 7). Dobzhansky and Sturtevant (1938) pioneered the latter type of analysis almost 70 years ago in a study of inversions in Drosophila pseudoobscura.

Since point mutations and rearrangement events act as parallel modes of evolution, they can be exploited concurrently to provide complementary perspectives on the relationships between the genomes under study. There are two important advantages of studying rearrangements, or chromosomal mutations: first, rearrangement analyses capture the evolution of a chromosome or a genome as a whole and not just locally. Second, because chromosomal mutations are rare events (Rokas and Holland, 2000), and because they are selected from a large set of possible candidates (e.g., there is a quadratic number of potential inversions that can affect a genome), they are less likely to suffer from homoplasy. This allows the reconstruction of scenarios even for deep phylogenies.

2. Algorithms and recent applications

There are different types of rearrangement events: some affect gene order (inversions, translocations, fusions, fissions, transpositions and inverted transpositions); while others affect gene content (insertion, deletion and duplication). Various methods have been developed to efficiently compute the rearrangement distance and sort a pair of genomes with equal gene content under different sets of operations; for

instance, with inversions only (Hannenhalli and Pevzner, 1999; Bader *et al*., 2001; Bergeron, 2001), with inversions, translocations, fusions, and fissions (Hannenhalli and Pevzner, 1995; Tesler, 2002), and with transpositions (Meidanis *et al*., 1997; Bafna and Pevzner, 1998). Some of these methods were then further adapted for multiple genome comparisons and phylogeny reconstruction under a maximum parsimony criterion: with inversions only (Siepel and Moret, 2001) and with inversions, translocations, fusions, and fissions (Bourque and Pevzner, 2002). See Figure 1 for an example.

Even without specifying a model of rearrangement events, the relative gene order can be used to define the breakpoint distance that can then be exploited, again under a parsimony criterion, for phylogenetic tree reconstruction (Blanchette *et al*., 1997; Blanchette *et al*., 1999). Although models that are not restricted to equal gene content are more comprehensive (see El-Mabrouk, 2005 for a review), they are typically more challenging algorithmically and have been restricted to a limited number of phylogenetic applications (Sankoff *et al*., 2000; Earnest-DeYoung *et al*., 2004).

Prior to the availability of detailed large genome sequenced data, rearrangement studies were restricted to the analysis of gene orders in genomes like mitochondria or chloroplasts (Palmer and Herbon, 1988; Sankoff *et al*., 1992; Bafna and Pevzner, 1995; Blanchette *et al*., 1999; Cosner *et al*., 2000). With the significant progress in large-scale sequencing and comparative mapping, rearrangement studies had to be reconfigured into a two-step process:

1. Identification of homologous syntenic blocks (HSBs) shared by the set of genomes under study.
2. Comparison of the respective arrangements of these common blocks in the different genomes.

The HSBs that need to be identified in step 1 can be obtained either from information on orthologous genes (Zdobnov *et al*., 2002) or directly from homologous sequences (Kent *et al*., 2003; Pevzner and Tesler, 2003a). In both cases, a threshold needs to be set to allow the HSBs to extend over small local discrepancies that could originate from different sources: erroneous assignment of orthologous genes (especially in large gene families), assembly errors, smaller rearrangement events falling outside the model (e.g., transposons), and so on. There are advantages to using orthologous genes to identify HSBs: it focuses the analysis on important regions of the genome, the thresholds are length independent and the blocks are less sensitive to repeat sequences. Similarly, there are advantages to using raw sequence data: it avoids annotation problems, it works in noncoding regions, it is less sensitive to gene families and finally it preserves more information on microrearrangements (rearrangements within HSBs) that can then be used as additional phylogenetic characters (Bourque *et al*., 2005).

Once the HSBs are identified, they can be processed in step 2 using algorithms for genome rearrangements in the same way genes were used previously. This two-step methodology was used to compare the human with the mouse genome (Pevzner and Tesler, 2003a) and suggested a larger number of rearrangements than previously expected (mostly intrachromosomal rearrangements). It also helped refine a model

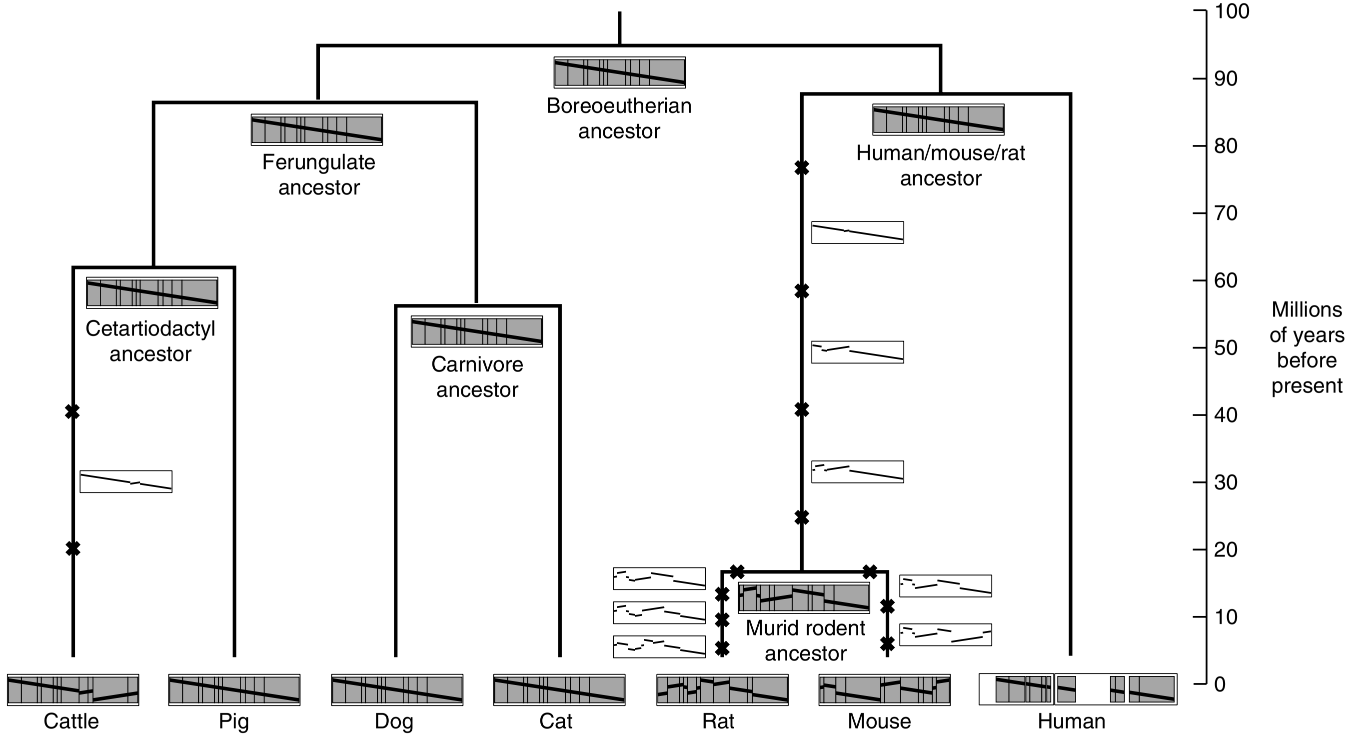

Figure 1 Mammalian X chromosome phylogeny. The arrangements of 11 homologous syntenic blocks, identified on the X chromosome of seven contemporary mammalian genomes (human, mouse, rat, cat, dog, pig, and cattle), are shown at the bottom of the tree. Blocks are drawn proportionally to their size in human and gaps are only shown in human to display coverage. A diagonal line traverses the blocks to show their order and orientation relative to human. The top of the tree exhibits the putative X chromosome ancestors in a most parsimonious inversion scenario as recovered by MGR (Bourque and Pevzner, 2002). The occurrence of an inversion is shown with a small cross on a branch of the tree but the exact timing of events on that branch is unknown. Hypothetical intermediate X chromosomes on a path are displayed using a white background. Data adapted from Murphy *et al*. (in press)

for chromosome evolution in which some breakpoints are reused nonrandomly (Pevzner and Tesler, 2003b; Larkin *et al*., 2003).

When more than two genomes are compared, rearrangement scenarios not only lead to the inference of phylogenetic relationships, they also provide rate estimates for the different branches of the tree and allow for the reconstruction of the putative architecture of ancestral genomes. A comparison of the human, mouse, and rat genomes (Bourque *et al*., 2004) confirmed the accelerated rate of interchromosomal rearrangements previously observed in lower-resolution studies of rodent genomes and predicted the genomic architecture of the murid rodent ancestor. The addition of the chicken genome acting as an outgroup (Bourque *et al*., 2005), allowed the reconstruction of the putative mammalian ancestral genome and further localized the lineage-specific chromosomal mutations. The analysis further revealed highly variable rates of genomic rearrangements across different branches of the tree with a particularly slow rate of interchromosomal rearrangements in the chicken lineage, in the early mammalian lineage, or in both.

Applications focusing on specific areas of the genomes allow for the identification of very detailed scenarios and possibly provide clues into the rearrangement mechanisms themselves. In the comparison of large vertebrate genomes, the X chromosome is a very interesting subproblem for studying chromosome evolution as it rarely exchanges genetic material with other chromosomes. Figure 1 shows the evolution of the X chromosome in seven mammalian genomes (human, mouse, rat, cat, dog, pig, and cattle); an example adapted from Murphy *et al*. (in press). This example highlights once again the unstable rate of genome rearrangements: about 85% (11/13) of the large-scale inversions affecting the X chromosome are found on the rodent branches whose total length only represents about 20% of the total length of the branches of the tree (corresponding to 500 Mya of evolution). What triggered and what are the consequences of this accelerated rate of inversions on the rodent X chromosome? These questions will require further work.

3. Limitations and future prospects

Many of the algorithms and applications described above still rely on a very simplistic model of evolution in which a limited set of equally likely operations are considered. Given the wealth of genomic data now available, it would be interesting, and challenging, to revisit these models, parameterize the different operations (in a way similar to what was done for mitochondria genomes (Blanchette *et al*., 1996)), and estimate their preponderance from the data itself. Such an experiment could potentially lead to a more realistic biological model of rearrangements but more importantly, it might provide new insights into the dynamics of genome evolution. In terms of making the rearrangement models more realistic, integrating other sources of information such as centromere and telomere positions could also prove valuable.

A related topic involves the development of a Bayesian framework for genome rearrangements. The methods described above have relied on a most parsimonious criterion but, in some cases, finding a most parsimonious scenario is insufficient.

For difficult problems (i.e., highly nonadditive trees), there are typically many optimal solutions and even the assumption that the actual history of rearrangement corresponds to a most parsimonious scenario becomes weak. A Bayesian approach has already been suggested for unichromosomal genomes (Larget *et al*., 2005) but has yet to be adapted to multichromosomal genomes. Such an approach would provide a richer description of the solution space but it would also allow a more natural parameterization of the rearrangement operations.

An emerging approach for chromosome phylogeny, similar in spirit to the analysis of breakpoints in that it does not require the specification of a rearrangement model, involves the analysis of conserved intervals in unichromosomal genomes (Bergeron *et al*., 2004). Although this approach does not analyze rearrangements directly, it can also identify phylogenetic relationships and reconstruct ancestral architectures by maximizing the conservation of the relative order of subsets of genes. It has the potential to be applicable to a wide variety of questions.

Another desirable improvement would involve the efficient expansion of genome rearrangement studies to genomes with unequal gene, or sequence, content. Although some preliminary studies have been moderately successful (Sankoff *et al*., 2000; Earnest-DeYoung *et al*., 2004), a tool to compare systematically whole eukaryotic genomes, not only on a set of common HSBs, is still needed. An intermediate solution could be to adapt multigenome studies to only require pairwise identification of common blocks.

As alternative methodologies for the analysis of genome rearrangements emerge, new systematic ways for comparing not only recovered phylogenies but also prediction at ancestral nodes will be required. Putative ancestors are difficult to compare because, in different studies, they are reconstructed using different sets of HSBs. So far, quality assessments have been limited to the analysis of predicted chromosomal associations (Bourque *et al*., 2004; Bourque *et al*., 2005; Murphy *et al*., in press) but it would be interesting to analyze more thoroughly the robustness of the rearrangement scenarios recovered when different choices of parameters, or completely different approaches, are used to generate HSBs.

4. Conclusion

Finally, as more and more detailed sequences and maps are released, lineage-specific breakpoint regions will be more systematically defined simply by the identification of HSBs. A recent study by Murphy *et al*. (in press) confirms that around 20% of breakpoint regions are reused and that those breakpoint regions are enriched for centromeres. The same study also finds interesting correlations between frequently rearranged regions, gene density, segmental duplications and recurring cancer breakpoints. Obviously, these evolutionary breakpoints represent an extremely rich source of information on the mechanisms regulating genome rearrangements and what can lead to their fixation in a population. As in-depth analyses of breakpoints regions are pushed further, the hope is that crucial information on these mechanisms will be uncovered. The challenge will then be to refine models and algorithms for genome rearrangements to employ that information proficiently.

Integrating statistical approaches in experimental design and data analysis

Ernst Wit and Raya Khanin
University of Glasgow, Glasgow, UK

1. Introduction

The main objectives of experimental design are reducing variation, eliminating bias, and making the analysis of the data and the interpretation of the results as simple and as powerful as possible. This should occur with the purpose of the experiment in mind and within the practical constraints. Principles of statistical design of experiments were first introduced by Ronald A. Fisher in the 1920s for designing agricultural field trials. The relevance of his ideas has only increased since then. This article elucidates the main principles of designing efficient experiments and the statistical analysis thereof. It uses microarray experiments as an example.

2. Design principles: between variation and bias

The common aim of many scientific experiments is to establish the activity of a *response* of interest across several *conditions* or *subpopulations*. For example, how do DNA sequence repeats vary across different positions on the human genome? Sometimes, the conditions or populations of interest are defined through an active intervention of the part of the scientist. In this case, conditions are typically referred to as *treatments*. For example, plant scientists may be interested in the change in expression profiles for Arabidopsis plants as a result of fertilizer, seed dormancy, or vernalization treatments. Sometimes, a proxy for the response is necessary if the response itself is not directly measurable. Average spot intensity on a microarray is typically taken as the operative definition of gene expression. Different proxies might have different characteristics, and sometimes it is useful to consider several proxies simultaneously.

Despite having a measurable quantity, it is typically infeasible to measure that quantity for the whole population of interest, nor is it likely that this quantity for all members of the population will be the same. This necessitates taking a *sample* and, at least as important, one that is *representative* of the population as a whole.

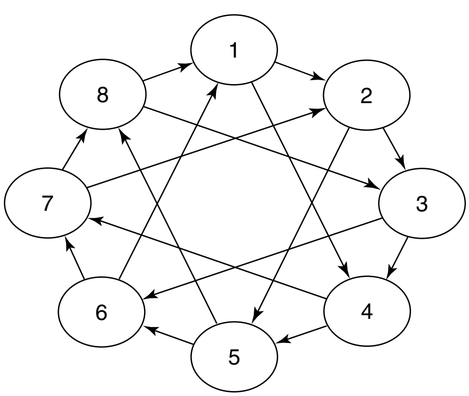
Representative means that it should embody the population variation, without any bias toward any particular group within it.

The ideas behind a representative sample are crucial for experimental design and can be described by means of several *design principles* (*see* Article 52, **Experimental design**, Volume 7):

1. *Replication:* When access to experimental material is limited or requires substantial resources, there might be the temptation to make several measurements on the same or a nearby experimental unit. Unfortunately, such observations are almost certainly very similar and therefore fail to reflect the full variation present in the sample. True replication, sometimes called *biological* replication in the context of biological experiments, is a necessary condition for obtaining a representative sample.
2. *Randomization:* If experimenters are let to decide for themselves which experimental units receive which treatment, it is possible that intentionally or unintentionally one condition is favored over another. By making the assignment of the units to the conditions subject to, for example, a coin flip, any such bias of the effects and their variances can be avoided.
3. *Blocking:* Often, it is impossible to get homogeneous experimental materials, in which case a subdivision in more or less homogeneous *blocks* should be considered. Microarrays come in print batches, DNA pools come from PCR amplification runs, and so on. Even though blocking factors are not of primary interest, it is important not to ignore the variation they introduce. Typically, it is prudent to model blocking factors such as print batches explicitly.
4. *Crossing:* If one experimental condition is always observed jointly with another, then it is impossible to decide whether the observed effect in the response is due to one or the other. This is called *confounding*. In order to avoid this type of ambiguity, it is essential to *cross* conditions with each other, that is, making sure that the levels of experimental conditions do not always appear in tandem.
5. *Balance:* It makes intuitive sense that in order to get the best results, each condition should be measured more or less an equal amount of times. Although not essential for inference, this type of *balance* has many computational advantages and is generally recommended wherever possible.

Following these general principles, one converts unplanned systematic variability into planned, chance-like variability. It protects against possible bias, and makes subsequent statistical analysis possible.

3. Several standard designs



To implement the design principles, one should be led first and foremost by the requirements of the experimental situation. Sometimes, it is possible to make use of several standard designs that satisfy automatically all the necessary design conditions.

If the experimental sample is from a homogeneous population, then no blocking is needed and the conditions can be randomly assigned to the experimental units.

This is called a *completely randomized design* and is most useful in only the simplest of scientific experiments. A commonly used design is the *randomized complete block design*, developed in 1925 by R. A. Fisher. In this design, the experimental units are subdivided into more or less homogeneous "blocks" and within each block the treatments are randomly assigned to the units.

Sometimes, the blocks are too small in order to apply all the conditions of interest within each block. This is typically the case in microarray studies, where each array is a block and at most two conditions can be measured within each array. *Incomplete block designs* (IBD) are aimed to deal with this situation. A Latin Square design is an elegant example of an IBD. It crosses the condition of interest with two blocking factors in such a way that the design is balanced, but not each combination of factors is observed.

Two-channel microarray experiments can be regarded as experimental designs with block-size two. If more than two conditions are of interest, then the assignment of conditions to arrays can be particularly tricky. Many standard incomplete block designs do not apply in this case. A simple class of interwoven loop designs has been suggested (Kerr and Churchill, 2001b) and shown to have excellent efficiency properties (Wit *et al*., 2005). Figure 1 shows an example of an interwoven loop design for eight conditions, which consists of lining up the conditions in the an imaginary circle (in any order) and by hybridizing each condition with the condition that is 1 step and with the condition that is 3 steps down the circle respectively. An interwoven loop design should always contain a 1-step circle in order to guarantee that all the conditions are connected. The other jump sizes can either be chosen intuitively or with some optimization function, such as od in smida library in R (Wit and McClure, 2004). An additional advantage is that by its very definition interwoven loop designs are dye-balanced and avoid the need of using inefficient dye-swap designs.

A-optimality score for contrasts: Tr[Inv(X′X)] = 13.
No of arrays = 16 No of conditions = 8.

Figure 1 An interwoven loop design is a special case of an *incomplete block design* with block-size two. This design has excellent efficiency properties and is balanced in the "nuisance" dye factor

4. Normalization and estimation of effects

If an experiment has been designed according to the above design principles, then *Analysis of Variance* (ANOVA) is a coherent technique to untangle the effects of interest from the nuisance effects (*see* Article 53, **Statistical methods for gene expression analysis**, Volume 7 and Article 59, **A comparison of existing tools for ontological analysis of gene expression data**, Volume 7). For example, in a microarray experiment, one would like to estimate the contribution of a particular condition to the gene expression of a particular gene, while correcting for the dye used for hybridization, the pin used for printing and the position of the spot on the array, and perhaps the batch number from which the microarray came. Classical ANOVA is by no means the only technique that is able to estimate the effects of interest. More recent (hierarchical) Bayesian modeling approaches are capable of doing very much the same thing. In this discussion, we focus on the classical ANOVA.

First of all, it is essential to determine the response of interest. Gene expression is typically measured as an optical intensity across several pixels (dual-channel arrays) or several probes (Affymetrix Gene Chip). Typically, these values are summarized in a single expression value, either by taking the mean, median, or by performing a somewhat more complicated operation (e.g., Li *et al*., 2003). Intensity is an essentially positive and often a multiplicative scale. We recommend applying a logarithmic transformation to the intensities before analysis (see also Kerr and Churchill, 2001a), although generalized log-transformations have also proved useful (Huber *et al*., 2003). For two-channel arrays, each array gives two expression values for each gene. Some studies interpret each channel as an independent observation (Kerr and Churchill, 2001a), whereas others prefer to take the log-ratio of each of these two values (Wit and McClure, 2004). The latter is safer, although more conservative.

Anything that contributes to variation in the response is known in the statistical literature as an *effect*. The idea behind ANOVA is to write the observed experimental quantity as a sum of contributing elements, which are the result of the varying experimental conditions. An *ideal* microarray experiment across n_c conditions and n_g genes would be modeled as

$$y_{ij} = \mu + G_i + C_j + (GC)_{ij} + \varepsilon_{ij} \quad i = 1, \ldots, n_g,\ j = 1, \ldots, n_c \tag{1}$$

where one typically assumes that the noise term ε is normally distributed with a fixed variance. The quantity μ stands for the overall expression level across the arrays G_i, measures the average deviation from that expression level μ for gene i, C_j, measures the average deviation from μ for condition j. Most importantly, $(GC)_{ij}$ stands for the differential expression of gene i with respect to level j. In particular, if for a particular gene i the quantities $(GC)_{ij}$ are zero across all j, then this gene is not differentially expressed under the experimental conditions. The term $(GC)_{ij}$ is an example of an *interaction effect*. This interaction effect allows the response to vary *differently* across the conditions for each of the genes.

Clearly, the model in equation (1) is too simplistic. Besides a random error term, practitioners know that in many experiments there are also systematic nuisance

effects. These nuisance terms are related to experimental conditions only partially under the control of the experimenter, such as, for example, a dye effect, a spatial effect, a pin effect, an array effect, or a batch effect. Under the assumption that each of these factors influences the signal additively, a more complete model for describing the observed gene expression involves additional terms for each of them, which is given by

$$y_{ij} = \mu + G_i + C_j + (GC)_{ij} + S_{s(i)} + B_{b(j)} + \cdots + \varepsilon_{ij}, \tag{2}$$

where $s(i)$ and $b(j)$ are functions that indicate the position of gene i on the array and the batch number of array j respectively. If the experiment uses printed dual-channel arrays, then also a dye term and a print pin term can be added. One can also add interaction terms of these nuisance effects. For example, a pin-batch interaction effect would model the fact that in a different microarray batch, the pin effects are probably different as the pins have most likely changed between different batch runs (Kerr and Churchill, 2001a).

The key element in an ANOVA is the F-test, evaluating the effect of each of the terms. These F-tests are typically summarized in an ANOVA table. See Table 1 for an example. Given that the number of terms in an ANOVA is limited, multiple testing is not particularly an issue and we recommend using the usual 0.05 cutoff for significance. Terms that have an associated p-value (last column) less than the cutoff are deemed important. Biologically most important are the individual estimates of the differential expression terms, that is, the condition-gene interactions. The individual differential expression terms can be put to further scrutiny.

There are two types of effects: so-called fixed effects and random effects. Fixed effects are most common and assume that the condition or treatment underlying the effect is some individual entity. Examples are gene effects, dye, and spatial effects. Random effects are used to model the effects of elements that can be considered to come from a larger population. The microarray batch used in an experiment can be considered as a particular sample from all possible batches made by the particular producer. Random effects are used when the effect of the individual levels of the condition or treatment are not of any particular interest, but the overall influence of them collectively is something to be taken into consideration. When both fixed

Table 1 ANOVA table for Arabidopsis example, using log gene expression ratios for 100 genes across the four distinct plant types and two different regions involving 16 microarrays

	Df	Sum sq	Mean sq	F-value	Pr(>F)
Dye	1	1314.42	1314.42	1302.02	0.000
Pin	3	1.09	0.36	0.36	0.782
Condition	7	72.81	10.40	10.30	0.000
Gene	96	101.01	1.05	1.04	0.378
Array	8	90.70	11.34	11.23	0.000
Condition* gene	693	3930.93	5.67	5.62	0.000
Type*gene	297	3474.29	11.70	11.58	0.000
Region*gene	99	134.99	1.36	1.35	0.018
Type*region*gene	297	321.65	1.08	1.07	0.235
Residuals	792	799.54	1.01		

and random effects are used in modeling a particular, one speaks of a mixed effects model.

Wolfinger *et al*. (2001) introduced a mixed effect model in a microarray context. The difference between fixed and random effects is not always clear-cut – for example, should pins be considered fixed or random effects? Using random effects results in somewhat more conservative estimates (larger standard errors), although typically it does not affect the estimates of the fixed effects, for example, the differential expression parameters GC_{ij}.

5. Design and analysis of a microarray experiment

We illustrate all the ideas in this article by means of a practical design and analysis of a stylized dual-channel microarray experiment. An experimenter wants to compare four genetically distinct types of Arabidopsis plants across two different regions of a country. It is of interest to compare the gene-expression values both across the genetic types as well as across region. We can therefore distinguish $4 \times 2 = 8$ separate conditions. Given the availability of 16 dual-channel microarrays, the way to obtain the best estimates of differential expression for each condition-pair is as shown in Figure 1 (Wit *et al*., 2005). Typical reference designs would merely measure each condition twice, whereas this interwoven loop design measures each condition four times. The microarrays contain 100 probes, associated with 100 different genes.

The resulting dataset contains 1200 log-expression ratios. The ANOVA table, shown in Table 1, can be obtained by most standard statistical software. We first consider the nuisance effects. By evaluating the p-values, it is clear that there is an important dye and array effect, although there is no evidence that the four pins used to print the arrays have any distorting effect on the gene expressions. After correcting for the array and dye effect, it is evident from the highly significant condition-gene interaction that there are at least some genes that are differentially expressed across the eight conditions. In particular, there is a lot of evidence for differentially expressed genes across the four Arabidopsis types. There is also evidence that the region from where the plants were harvested affects the gene expression, although no synergetic effect on gene expression of genetic type and region is observed.

6. Conclusions

In order to avoid obtaining useless data, it is essential to integrate the statistical analysis with the design of any complex scientific experiment. For example, sources of variation cannot be estimated if they are confounded in the experimental design. Using ANOVA, or Bayesian equivalents, has the advantage of combining the normalization process with the data analysis. Considerations of optimal design can be employed to obtain the most accurate estimates of the parameters of interest.

Introductory Review

Mass spectrometry and computational proteomics

Vineet Bafna

Knut Reinert
Free University Berlin, Berlin, Germany

1. Introduction

Computation occupies a central role in the interpretation of high-throughput biological data, and proteomics is no exception. It can also be argued that *mass spectrometry* is now the tool of choice for proteomics, with applications to peptide sequencing, protein structure prediction, protein–protein interactions, (relative) protein expression, and many others. Continued improvements in instrumentation and computational technologies will only help accelerate this trend. Indeed, the chemistry Nobel prize in 2002 was awarded for the development of protein ionization methods in mass spectrometry. While rewarding individual accomplishments, the awards were also a recognition of the immense potential of this field.

In this overview, we summarize algorithms for interpreting mass spectrometry (MS) data. This short overview is not intended as an introduction to the technology itself or to proteomics (see for example (Siuzdak, 1996; Wilkins *et al*., 1997)). Instead, we will provide an abstract overview of MS data in order to describe key algorithmic ideas required for its interpretation. Owing to space limitations, we will concentrate on three applications: *protein identification, protein interactions*, and *differential analysis of protein expression*.

2. MS technology

The mass spectrometer is a device that measures the mass (actually, the mass-to-charge ratio) of an ionized molecule. Its key components are a source for sample introduction and ionization (typically MALDI (Matrix Assisted Laser Desorption Ionization) or ESI (ElectroSpray Ionization)), and a *mass analyzer* for measuring the mass (e.g., Ion Trap, TOF (time of flight), Quadrupole, and Fourier transform (FT_MS)). The conceptual question one might ask is the following: how can a

device that essentially measures mass be used in diverse applications like protein sequencing, expression, and structure?

To answer this, one must note that while these devices are conceptually simple, they now offer extremely high mass accuracy and resolving power. Various protocols can be used to obtain a set of characteristic masses that would be diagnostic for a protein. In *Peptide Mass Fingerprinting* (PMF), the protein is enzymatically digested and the peptide masses are recorded using a single mass spectrometric measurement (MS). Every protein will have a characteristic set of digested peptides, and correspondingly, peptide masses. For more complex mixtures, this procedure is not sufficient and instead multiple stages of mass spectrometry are applied (tandem MS (MS/MS) or MS^n).

In tandem mass spectrometry (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5), the peptides (from an enzymatically digested protein mixture) are ionized with one or more units of charge, as in single-stage MS, and a specific peptide is chosen for fragmentation by *collision-induced dissociation* (CID). Fragments retaining the ionizing charge after CID have their mass–charge ratio measured in a second stage of mass spectrometry. Since peptides typically break a peptide bond when they fragment by CID, the resulting spectrum contains information about the constituent amino acids of the peptide.

The fragmentation of the peptide in CID is a stochastic process governed by the physicochemical properties of the peptide and the energy of collision. The charged fragment can be inferred by the position of the broken bond and the side retaining the charge. In Figure 1(b), the N-terminal a_1, b_1 and c_1 fragment ions and the C-terminal x_{n-1}, y_{n-1}, and z_{n-1} fragment ions are shown. While *a,b,y* represent the commonly occurring fragments, a high-energy collision often

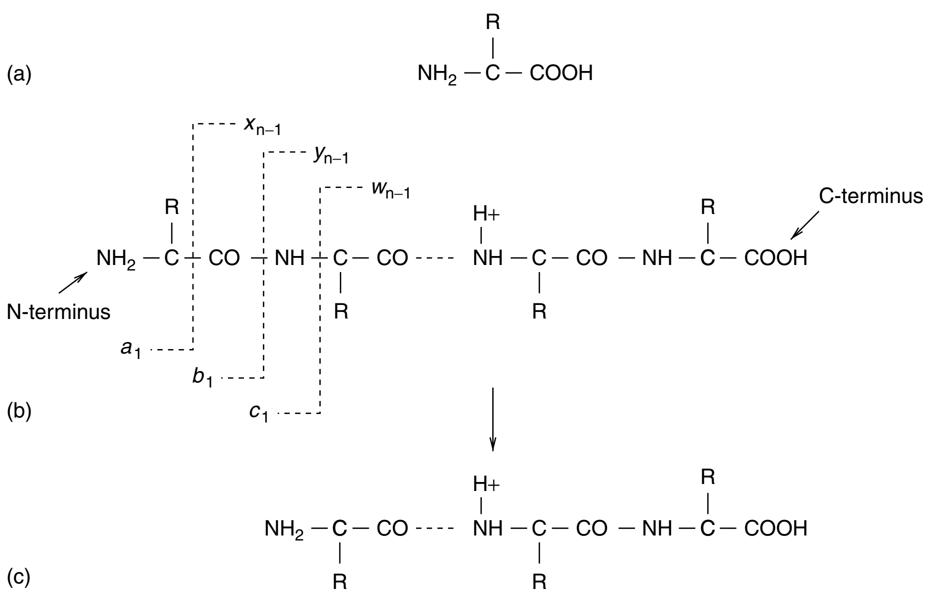

Figure 1 (a) The structure of an amino acid. (b) An ionized peptide. (c)y_{n-1}^{+} ion

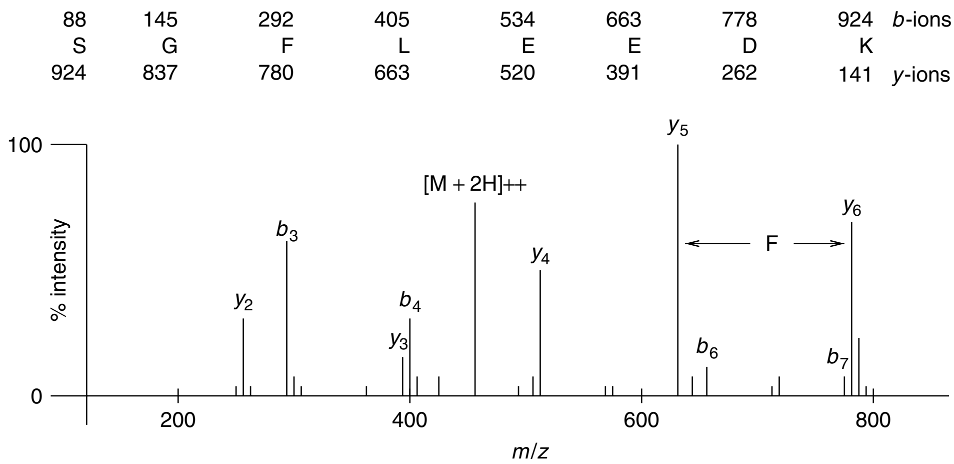

Figure 2 MS/MS spectrum for peptide SGFLEEDK

results in other fragments, including *internal* fragments formed by breakage at two points, fragments formed by breaks in side chains, and neutral molecule losses from fragments, including H_2O, and NH_3. One or more of these fragments retain the charge unit(s) and their mass–charge ratio is registered. Figure 1(c) shows the single charge being retained by y_{n-1}. In a single experiment, many charged fragments are formed by CID of multiple copies of the same peptide. The aggregate of the mass–charge ratios detected is called the *MS/MS spectrum*. A cartoon MS/MS spectrum for the peptide SGFLEEDK is shown in Figure 2. It helps illustrate how the MS/MS spectrum can be used to determine the sequence of amino acids of a peptide. Note that the difference in mass–charge ratio of the adjacent singly charged y-ions, y_5 and y_6, is exactly the mass of the residue F. The algorithmic challenge is to use the MS/MS data in the presence of noise, incomplete fragmentation, and mixed prefix, suffix, and internal ions, to provide unambiguous identification.

3. Protein identification

MS/MS might not be necessary if a relatively simple mixture of proteins is being analyzed. Instead, PMF can be used with every protein containing a characteristic set of peptide masses. Two problems complicate this simple picture. First, only a small fraction of the peptides are typically ionized and detected by MS. Second, the observed peptides are sometimes from multiple (2–10) dominant proteins in the mixture. These issues are partially resolved using a Bayesian probabilistic model that assigns a likelihood of a protein sequence, given a spectrum of peptide masses (Perkins *et al*., 1999). The protein with the highest likelihood is then reported. In order to deal with multiple proteins, the process is repeated after “removing” the peaks that matched the first protein. For many proteomic applications with complex mixtures of proteins, single-stage MS is gradually being supplanted by tandem and higher-order mass spectrometry as the more reliable method for protein sequencing.

The core of most of the software programs for analyzing tandem MS data contain an implementation of the following three modules: *interpretation, filtering*, and *scoring*. In the interpretation module, the input is an MS/MS spectrum and the output is an *interpreted spectrum* containing meta-information that can be reliably inferred from the spectrum. It may include parent peptide mass, partial or complete sequence tags, and combinations of sequence tags and molecular masses. The filtering module takes the interpreted spectrum and a peptide sequence database as input and filters out most of the peptides, leaving a small list of *candidate peptides* that might have generated the MS/MS spectrum. Finally, the scoring module takes the list of candidate peptides MS/MS spectrum as input and returns a ranking of the candidate peptides along with a score and possibly a p-value (probability that the score was achieved by random chance). If significant, the highest scoring peptide is the correct interpretation. As the peptide sequences have relatively low redundancy, the identification of the sequence of one or two peptides is usually sufficient to identify the protein. Certainly, *scoring* is the key module and is under active research (Bafna and Edwards, 2001; Elias *et al*., 2004; Eng *et al*., 1994; Tabb *et al*., 2001). However, most existing toolkits use some aspects of all three modules. With an increase in the size of databases, and growing interest in posttranslational modifications, algorithms for interpretation and filtering are coming to the fore.

3.1. De novo interpretation

We take a general view by defining interpretation to be any sequence information gleaned from an analysis of the spectrum. The class of *de novo sequencing* algorithms attempt to reconstruct the entire peptide sequence via interpretation without the use of a peptide database (see for example (Bafna and Edwards, 2003; Bartels, 1990; Chen *et al*., 2001; Dancik *et al*., 1999; Fernández de Cossio *et al*., 1995; Johnson and Biemann, 1989; Taylor and Johnson, 1997)). To understand how this is done, consider the simple case in which all observed fragments are b-type prefix ions. If all the fragment ions were present, then the sequence could be read simply by reading the ladder of increasing masses and assigning residues to mass differences between adjacent peaks. The complexity comes from the fact that (1) there are multiple fragment ion types, including internal ions and different charge states; (2) the prefix ions cannot a priori be separated from the suffix ions; and (3) not all positions are along the peptide chain fragment.

A key algorithmic idea that deals with mixed prefix and suffix ions is the prefix residue graph, first described in Dancik *et al*. (1999), but implicit in (Bartels, 1990; Taylor and Johnson, 1997). If we knew the ion type for a spectral peak, it would uniquely define the residue mass of a prefix (PRM) of the peptide. Thus, for all possible interpretations of a peak, a node labeled with the PRM value is added to the graph and a directed edge is drawn from node u to node v if PRM[v]-PRM[u] corresponds to a residue mass (adjacent fragments) or if it is close to 0 (identical fragments). Each edge is labeled with the ϵ or the appropriate amino acid. Thus, any path in this graph corresponds to a de novo sequence interpretation simply by concatenating the non-ϵ edge labels. A multitude of paths are possible, and scoring and ranking these paths is critical to correct interpretation.

One argument against this approach is that a peak may be used multiple times in a path with different interpretations. Resolving this problem in a general scenario is equivalent to constructing paths in which certain pairs of nodes are forbidden, which is known to be computationally hard (Garey and Johnson, 1979). However, Chen *et al*. (2001) made the observation that the forbidden suffix–prefix pairs for tandem MS are nonintersecting. This observation allowed them to give a dynamic programming solution for finding paths with forbidden pairs. Bafna and Edwards (2003) extended this approach to include multiple ion types (*a,b,y*, and all the neutral losses) in the interpretation. While pure de novo sequencing of spectra has seen many improvements, tandem mass spectra usually do not have enough information to make an unambiguous identification. Searching a database of candidate peptides (as described in the next section) constrains the possibilities enough to make such identification possible. However, de novo interpretation is still useful in some situations. It can be used to generate sequence tags that can then be used as additional filters to improve database search (Mann and Wilm, 1994; Tabb *et al*., 2003; Taylor and Johnson 1997), especially for modified peptides. Also, for pure proteins whose sequence is not yet available in databases, a *de novo shotgun* sequencing of overlapping peptides obtained via multiple enzymatic digestion holds promise (MacCoss *et al*., 2002).

3.2. Scoring spectra against peptides

When the protein sequence of interest is present in a database, one can interpret an MS/MS spectrum by computing the correlation between the spectrum and a hypothetical spectrum of each peptide. The so-called database searching algorithms (Bafna and Edwards, 2001; Eng *et al*., 1994; Fenyo *et al*., 1998; Mann and Wilm, 1994; Pevzner *et al*., 2000; Tabb *et al*., 2003) rely on this technique for interpretation and have been extremely successful. Sequest (Eng *et al*., 1994) is the prototypic database search method. It presents a model for the generation of hypothetical spectra, and a correlation function for scoring. If the spectrum is of poor quality, there is no guarantee that the top scoring peptide is the correct interpretation. Subsequent algorithms (Bafna and Edwards, 2001; MacCoss *et al*., 2002; Perkins *et al*., 1999) therefore included a p-value along with the raw score to give a probability of that score arising from a randomly chosen peptide. Further improvements in scoring have come from an analysis of the physicochemical rules of fragmentation, such as "neutral losses are more likely in the presence of acidic or basic residues", and "proline-directed fragmentation". The algorithm in Scope (Bafna and Edwards, 2001) presents a model for quantifying these rules as probabilities and efficient scoring with the probability functions. Recent work is directed toward data mining and learning techniques to optimize a score function, as well as the use of intensity values in scoring (Elias *et al*., 2004).

3.3. Filtering

The goal of filtering is to scan a database of peptide candidates and quickly filter out the vast majority of them while retaining the true peptides for detailed scoring.

While most algorithms include simple filters typified by parent mass, immonium ions, and matching peaks, this topic was not actively researched until recently. With exponential growth in the number of spectra and sequence databases, this is only now beginning to see active research. Pre-indexing sequence databases is useful in removing redundant peptide information and efficient search for candidates. One approach to indexing is the use of suffix trees (Edwards and Lippert, 2002; Lu and Chen, 2003). Other approaches include the use of sequence tags as filters in a database search (Mann and Wilm, 1994; Tabb *et al*., 2003; Taylor and Johnson, 1997).

4. Differential analysis of protein mixtures

Differential analysis of proteome expression levels has been developing rapidly over the last years. The current standard separation technique in proteomics is undoubtedly gel electrophoresis, which is typically used together with mass spectrometry for identification of the proteins separated on the gel. While this technique is well established and is in use in most major proteomics facilities, it has disadvantages in the context of high-throughput settings. In particular, the difficult handling of the gels prompted several proteomics facilities (mostly in commercial settings (Domon *et al*., 2002), but also in academia (MacCoss *et al*., 2003; Sickmann *et al*., 2003)) to use High Performance Liquid Chromatography (HPLC)-/MS-based techniques instead (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5). In these approaches, the liquid-chromatographic separation in an HPLC column replaces the separation on the gel. In contrast to gels, HPLC systems allow for direct coupling to a mass spectrometer, thus greatly simplifying the automation of the whole analytical process. In the shotgun approach, the proteins are usually fully digested in order to simplify and unify sample preparation. The combined use of the complementary expression techniques (mRNA expression, gel-based MS, and HPLC-based MS) will yield further progress in diagnostics and systems biology.

The analysis of HPLC/MS data for differential analysis of protein expression poses many challenging computational problems. Note that measuring protein expression using MS techniques is generally difficult. Different peptides have different capacity to retain charge, and so peptides with identical concentration might show up with very different intensities in the spectrum. However, the relative intensity of peaks for the *same* peptide is predictive of relative expression of that peptide in different samples. To use this fact in differential analysis, consider the output of an HPLC/MS run. As the peptides elute off the column, MS spectra are acquired in real time. The data can be represented as a two-dimensional (2D) spectrogram, or map, with the two dimensions being LC retention time (RT) and m/z. As a peptide typically elutes over a fixed time span and has a fixed m/z, a "spot" on this map corresponds to the elution of a peptide. The intensity of the spectra provides a third dimension. Two maps from different samples (normal and diseased) will have similar spots corresponding to the commonly expressed peptides and spots of differential intensity corresponding to proteins whose expression levels

have changed. Geometric matching algorithms are used to match the similar spots, and their intensities are used for normalization, sometimes with internal standards. Once this is done, the relative intensities of differentially expressed peptides can be computed. This basic idea can be made to be statistically robust by choosing multiple samples from both categories. This is analogous to the use of 2D gels for separation with important differences. It is the peptides and not proteins that are being separated. As the retention time and mass measurements are typically accurate, the reproducibility of maps is much higher than 2D gels. Algorithms for creating and comparing various 2D maps and for computing relative intensities of a few thousand differentially expressed peptides have been used to successfully identify differentially expressed peptides in tumor cells (Domon *et al*., 2002). The key components of these algorithms include the deconvolution of peaks from different but overlapping peptides and creation, normalization, and comparison of multiple maps to identify differential expression.

An alternative approach uses some type of differential mass labeling of the two samples to provide uniform experimental conditions (*see* Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5). The two samples are labeled differently, for example, by introducing stable isotopes such as ^{15}N, ^{2}H, ^{13}C, or ^{15}O into the proteins of one of the samples (Berger *et al*., 2002; Oda *et al*., 1999). Other approaches are mass-coded abundance tags (MCAT (Cagney and Emili, 2002)) and isotope-coded affinity tags (ICAT, (Gygi *et al*., 1999)), where the mass difference is introduced by derivatization of specific amino acid residues. The samples are then mixed and subjected to HPLC/MS. In the resulting maps, each peptide should occur in paired "spots" that are very similar in RT and have a mass offset that corresponds exactly to the differential mass of the labeling tags. This simplifies the computation somewhat, as comparison of two LC/MS maps is not required. For statistical robustness, one might still need to perform multiple such experiments and compare maps in order to identify differentially expressed peptides unambiguously (Domon *et al*., 2002).

5. Protein structure: cross-linking

MS technologies are clearly creating an impact on protein identification and quantification. Can we also use them for protein structure determination? X-ray crystallography and NMR remain the dominant techniques in this field, but much work remains to be done. These techniques require large amounts of pure analyte, and even if this is available, it can take many months until the structure is determined. On the other hand, it is theoretically possible to determine the tertiary structure of a protein computationally, given enough interatomic distance information (Cohen and Sternberg, 1980). Even partial information often proves to be helpful. To acquire this distance information, the mass of *cross-linked* peptides can be measured (Young *et al*., 1997), and using this information, the sequence of the cross-linked complex can be determined. Cross-linking is a method in which certain molecules are used to specifically link two peptides. The identification of cross-linked peptides in a folded molecule then provides constraints on the spatial distance of the peptides in a folded state. One approach to identifying cross-linked

peptides is simply to find all pairs of peptides whose mass sum (plus the mass of the linker) equals the mass of the parent cross-linked molecules. Among these, a peptide pair is chosen whose theoretical spectrum best correlates with the measured spectrum (Chen *et al*., 2001). These additional constraints can be used to improve tertiary structure prediction.

6. Conclusion

We conclude by reiterating that mass spectrometric techniques are key to proteomic explorations, and computational algorithms for analyzing MS data are crucial to further development of this technology. Mass spectrometry is a dynamic and evolving field and it is likely that many of the data sets and applications described here will be outdated in the coming years. Nevertheless, it is our hope that the basic understanding of MS principles and key algorithmic components will continue to be useful for future proteomic applications of mass spectrometry.

Specialist Review

Experimental design

Kevin K. Dobbin and Richard M. Simon
National Cancer Institute, Bethesda, MD, USA

1. Introduction

Experimental design issues for dual-label and single-label microarray experiments are discussed, including identification of research objectives, avoidance of confounding, allotment of samples to arrays and dyes in dual-label experiments, dye bias, pooling RNA before labeling, and determination of the number of arrays required to achieve the study objectives.

2. Objectives

The first step in designing a microarray experiment is to identify the goals of the experiment. There is no one design that will be appropriate for every experiment, but the optimal design for a particular experiment will depend on the research questions being addressed. As the size and scope of microarray studies grow, so does the range of questions that researchers are asking. It is not possible to be comprehensive here in discussing study objectives, but it is useful to identify a few general types of objectives often seen in microarray research.

Class comparison objectives apply to studies of collections of specimens that come from two or more predefined classes, types, or conditions. The defining aspect is that the classes are known ahead of time, independent of the gene expression data, and that the research question is: which genes are expressed differently in the different classes? For example, Hedenfalk *et al*. (2001) compared primary tumors from two classes of women, those who carried the BRCA1 mutation genotype and those who carried the BRCA2 mutation genotype. One goal of the study was a class comparison goal, namely, to discover a set of genes that were expressed differently in the two genotypes. Other examples of studies with class comparison objectives include: (1) Golub *et al*. (1999) identified genes expressed differentially between specimens of acute myelogenous leukemia (AML) and specimens of acute lymphocytic leukemia (ALL); (2) Ross *et al*. (2000) compared expression profiles of cancer cell lines from different tissues of origin. In these studies, class comparison was often not the only goal, but there were other goals as well, such as class prediction.

Class prediction objectives can apply either to studies of collections of specimens from predefined classes or to studies in which some clinical outcome is measured

for each individual from which a specimen was obtained. The defining aspect is that the research question is: can we construct a prediction rule for the specimens that will predict, from the gene expression data alone, the likely class or outcome for an individual? The ultimate goal is usually to develop a rule that can be used on future individuals for whom the classification or outcome data is not available. The Golub *et al.* (1999) paper also provides an example of a class prediction objective; the differentially expressed genes discovered in the class comparison phase were used to develop a multigene class predictor that distinguished between AML and ALL, and the predictor was applied to an independent set of tumors to assess the predictive performance. Rosenwald *et al.* (2002) developed a molecular predictor of survival after chemotherapy on the basis of biopsy samples from diffused large-B-cell lymphoma patients.

Class discovery objectives can apply either to studies in which there are no predefined classes for the specimens, or in which the current classification system is deemed inadequate. The defining aspect is that the research question is: can we discover a new classification system for these specimens based solely on gene expression data? Bittner *et al.* (2000) applied cluster analysis techniques (*see* Article 54, **Algorithms for gene expression analysis**, Volume 7) to the gene expression profiles of a collection of melanoma samples to identify a novel classification system for this otherwise homogeneous group of specimens, suggesting a gene expression–based taxonomy.

Another type of class discovery study addresses the research question: can we use what we know about the function of some genes to figure out the function of other genes (*see* Article 60, **Extracting networks from expression data**, Volume 7)? Or, what genes are coregulated in these samples? These questions are typically approached by applying cluster analysis to the genes instead of the samples.

3. Confounding

In an ideal microarray experiment, tissue handling and cutting, RNA extraction, reverse transcription and labeling, and array hybridization would all be performed at about the same time, under identical experimental conditions. For such an experiment in a class comparison setting, observed significant differences between the classes in gene expression could safely be attributed to real biological differences between the classes. But it is common that this type of ideal experiment is not possible, that not all microarrays used will be analyzed at the same time, that the microarray chips used may not all be uniform, that reagents may vary over the course of the experiment, and so on.

If the microarray assay conditions vary, then it is still possible to construct a well-designed experiment by ensuring that the assay conditions are not confounded with the goals of the experiment. For instance, suppose that one has two classes of specimens one wishes to compare, that there are 10 specimens from each class, and that there are also 10 microarrays from each of the two different chip versions that are to be used. An experiment that assigns the samples from one class to one chip version and the samples from the other class to the other chip version would be poorly designed because one would not know whether to attribute observed differences

to chip versions or to the classes. Chip version and classes would be completely confounded, that is, their effects would be inextricably mixed together. A well-designed experiment, in this situation, would be one in which each class is assigned five chips from each version. Then observed differences between the classes could not be attributed to the chip version, and one could separate out the effects of the different chip versions from the biological differences between the classes.

4. Dual-label microarray experiment designs

Dual-label systems present design issues not encountered by single-label systems. Each array in a dual-label system has two channels, one corresponding to each dye label. The motivation for using two labels instead of one is that it allows one to eliminate spot-to-spot variation – due to quality, size, and location of spots – from comparisons of interest. The result has much greater power in class comparison experiments and greater ability to identify true clusters in class discovery than if a single dye was used. The resulting data structure, with a large variation between measurements from different spots and a small variation between the two measurements on the same spot, is called a block structure by statisticians, with the spots on the microarray serving as the blocking factor whose variability is blocked out of the comparisons of interest.

We will focus here on two types of designs for dual-label experiments, reference designs and balanced block designs, because for most experiments where the goal is class comparison, class prediction, and/or class discovery, one of these two designs will be optimal. Variations on these designs, such as dye swaps and technical replicates, will be discussed below. Other designs have been proposed, such as all-pairs designs (Yang and Speed, 2002), and loop designs (Kerr and Churchill, 2001).

4.1. The reference design

Reference design dual-label microarray experiments utilize multiple aliquots from a single RNA source, called the reference, which are applied to each microarray and are usually all labeled with the same dye. The role of the reference is sometimes not clearly understood. The size and location of a spot on a microarray is a major source of variability in these types of experiments. The role of the reference is to provide an estimate of this “spot” effect for every spot on every array. Consider the situation for a single gene. In all of the reference aliquots, this gene has the same expression level; therefore, differences in the expression level for this gene on different arrays can be attributed to the combination of spot size, quality, and location effects that together make up the spot-to-spot variation. Hence, for this gene, the spot-to-spot variation is well represented by the variation in the expression of the reference sample over the spots (assuming that the gene is expressed at a sufficiently high level in the reference sample). This allows one to correct for this source of variability when comparing the samples in the nonreference channels. Without the reference, it would not be possible to correct for this source of variation,

and the noise would effectively drown out much of the effects of interest for which one is looking.

The reference sample does not have to have a biologically meaningful interpretation, but it should be selected so that, in general, the genes expressed in the nonreference samples are also expressed in the reference sample. In order to get a good correction for the spot-to-spot variation, one needs some gene expression in the reference sample for that gene, otherwise there will be a universally low gene expression in the reference channel regardless of differences in the size, quality, and location of the spots, and the reference channel will not reflect the "spot" effects well. Therefore, genes with low or no expression in the reference channel will provide relatively noisy comparisons between the nonreference samples.

4.2. The balanced block design

The reference design may appear ideal because of the simple and intuitive way in which it allows one to estimate the spot-to-spot variation and eliminate it from comparisons of interest. But, in fact, spot-to-spot variation can also be estimated and eliminated from other types of designs. Although the estimates in these other types of designs may not be as intuitive as in the reference design, they are equally valid and can in fact result in considerable improvement in efficiency for class comparison experiments. The most efficient designs for class comparisons are balanced block designs. Other types of designs that have been proposed in the literature are not as efficient (Dobbin and Simon, 2002).

A balanced block design does not use a reference sample. Instead, a single aliquot from each biological sample (e.g., from each person or each mouse) is taken, and the samples are arranged so that samples from any two classes are paired together the same number of times over the microarrays. In the case of just two classes, this means that a sample from each class is paired together on each array. As discussed in the dye bias section below, half the samples from each class should be tagged with Cy3 dye, and the other half with Cy5 dye.

Examples of a reference design and a balanced block design are given in Tables 1 and 2.

4.3. When to use a reference design and when to use a balanced block design

The reference design is the most commonly used design in dual-label microarray experiments. There are several advantages to the reference design that make it particularly appealing to scientists who may not have access to a trained biostatistician or bioinformatician to consult with on the design or analysis of their experiment: (1) some microarray data analysis software packages assume that a reference design was used, and analyzing data from a different type of design with these packages may not be straightforward; (2) reference designs do not require that the investigator stipulate ahead of time what particular comparisons are going to be of primary interest, and hence allow for greater flexibility than designs (such as the balanced block design), which do require the classes to be identified ahead of time

Table 1 Reference design example. R is the reference sample. A, B, C, D, E are the five different classes being compared. There are two different samples from each class

Array	1	2	3	4	5	6	7	8	9	10
Cy3	R	R	R	R	R	R	R	R	R	R
Cy5	A	B	C	D	E	A	B	C	D	E

Table 2 Balanced block design example. A, B, C, D, E are the five different classes being compared. There are four different samples from each class

Array	1	2	3	4	5	6	7	8	9	10
Cy3	A	C	A	E	B	D	B	C	E	D
Cy5	B	A	D	A	C	B	E	D	C	E

and which may also lock the investigator into one particular type of comparison to the exclusion of other possible comparisons (for instance, one may be locked into a comparison of different tumor grades when the real interesting comparison turns out to be different tumor stages – but it may not even be possible to make this comparison after a balanced block experiment is run with grade as the comparison of interest); (3) if samples are analyzed at different times, then there may be no easy way to adjust for these differences unless one has the reference sample to serve as a baseline for the comparisons.

If class discovery is a goal of the experiment, and the samples are to be analyzed using cluster analysis, then the reference design has been shown to be superior to other designs that have been proposed (Dobbin and Simon, 2002). The reason for this is that effective cluster analysis depends on having good estimates of the distance between every pair of samples. In a reference design, the distance between any two samples is measured with the same efficiency because that distance only involves measurement error related to two arrays, corresponding to the arrays for each of the samples; this is because the repeated reference sample on each array can be used to "connect" any two arrays. Other designs have less direct "connections" between the samples that involve more arrays and hence more measurement error. Because some of the distances in these alternative designs will be measured quite inefficiently and so will be very poorly estimated, a cluster analysis algorithm will have a hard time picking up the structure in the data, as we have shown in simulations (Dobbin and Simon, 2002). Importantly, the balanced block design will have very poor class discovery performance because the spots, that is, the sources of greatest noise in these experiments, are confounded with the individual sample effects, completely obscuring the true distances between samples on different arrays.

Things are less straightforward if class comparison is the major goal of the experiment. In this case, the best design depends on what the limiting factor is in the experiment. Arrays are the limiting factor of the experiment if one has plenty of samples (or could produce plenty of samples), but owing to expense or other logistics, one can only run a fixed number of arrays. On the other hand, samples are the limiting factor if one only has access to a fixed number of samples, and

Table 3 Relative efficiencies of balanced block and reference designs. Efficiency of block design divided by efficiency of reference design, so that a relative efficiency over 1 indicates a block design that is more efficient. Ratio of biological variation to experimental error variation assumed to be 4 (see Dobbin and Simon, 2002)

Relative efficiencies		Number of varieties	
		2	3
Limiting factor	Same number of arrays used	2.4	1.8
	Same nonreference samples used	1.2	0.9

array expense or logistics is a relatively minor concern – one just wants to measure these samples as well as possible.

For a class comparison experiment in which arrays are the limiting factor, a balanced block design can be significantly more efficient than a reference design. This means that the resulting list of differentially expressed genes will potentially have far fewer "false positives" – genes that are not truly differentially expressed – and will be missing far fewer "false-negatives" – genes that truly are differentially expressed but which do not show up on the gene list because the difference is drowned out by experimental error variation. Table 3 shows the relative efficiencies for a balanced block compared to a reference design. For two classes, the relative efficiency is 2.4, indicating that it would require more than twice as many arrays with a reference design to achieve the same efficiency as a balanced block design.

For a class comparison experiment in which the samples are the limiting factor, the efficiency differences between a balanced block and reference design are much less dramatic (see Table 3, second row). This is partly because the reference design uses twice as many arrays, and hence it will be more expensive and labor intensive than the balanced block design. With three or more classes, the reference design is more efficient, and seems preferable overall. With two classes, the reference design is slightly less efficient, but this may not offset some of the advantages described in the first paragraph of this subsection.

5. Dye bias and the use of dye swap designs

Several definitions of dye bias have been used in the literature: (1) the tendency of one dye to appear brighter overall across genes (although this should be removed by proper normalization); (2) the tendency of spots with different overall intensities to display different relative efficiencies of the two dyes (which can be adjusted for using intensity dependent normalization such as lowess); (3) bias for a particular subset of genes caused by an interaction between the gene and the dye being incorporated. This creates dye bias for certain genes, but the dye bias for a gene is the same in all the samples; (4) bias caused by an interaction between genes and the dyes that is different for different samples. We will restrict attention to definition (3), and we refer to this type of dye bias as a gene-specific dye bias to distinguish it from (1) and (2). Bias of type (4), which could be called gene-and-sample-specific dye bias, could not be removed statistically from the comparisons

of the different samples, so we will not discuss this type of dye bias here. Several authors have investigated gene-specific dye bias and found that it does seem to exist, but generally tends to be small in quantity (Dobbin *et al*., 2003a,b Tseng *et al*., 2001).

For class comparison experiments, gene-specific dye bias will not affect comparisons between classes of samples labeled with the same dye. Hence, gene-specific dye bias will not affect the identification of differentially expressed genes in single-label experiments or in dual-label reference design experiments (for comparison of classes of nonreference samples). Gene-specific dye bias may affect cluster analyses in class discovery experiments in either single-label or dual-label platforms with a correlation metric because intensity differences between genes may be influenced by gene-specific dye incorporation efficiency.

For class comparison experiments using a balanced block design, gene-specific dye bias can be eliminated from the class comparisons in dual-label systems by labeling half (or nearly half, if odd number) of the samples from every class with each dye, and adding a dye bias term to the model. There is no need to dye swap individual arrays (i.e., run the same two samples with the labeling reversed) to eliminate the dye bias. In fact, dye swapping individual arrays will result in a loss of efficiency compared to running new arrays with different samples (Dobbin *et al*., 2003a).

Finally, if, in a dual-label system, comparisons between the reference sample and the nonreference samples are of interest, then dye bias adjustment can best be made by running dye swaps on some, but not all, arrays (Dobbin *et al*., 2003a).

6. Pooling samples

In some situations, there is not enough RNA available from individual specimens to run the microarray assay. This problem can be overcome either by RNA amplification, or by pooling different RNA samples together until there is enough RNA for an array. Pooling samples, in this way, can be a viable alternative to RNA amplification. In order to perform statistical inference in a class comparison setting, it is necessary to construct several independent pools from each class or condition. Two pools are independent if there is no overlap in the sources from which the pools are constructed, for example, if RNA from three mice is used to form each pool, then no two pools have a mouse in common.

Sometimes the motivation for pooling is not that there is inadequate RNA from individual samples to run the microarrays, but that by pooling it is hoped that the cost of the experiment will be reduced because fewer microarrays are required. For instance, an experiment with 12 samples from each of two classes would require 24 single-label microarrays; by pooling pairs of RNA samples together, one can reduce the number of arrays required to 12, 6 for each class. The pooled samples will also show less variation because, by pooling samples, the biological variation is reduced. But the improvement in power usually associated with such a reduction in variance is offset somewhat because power is also related to degrees of freedom for error, and the degrees of freedom are reduced from 22 in the 24-array experiment to 10 in the 12-array experiment. In fact, in order to get the same power as in the

Table 4 Number of arrays and samples required for various pooling levels. An independent pool is constructed for each array, so that no sample is represented on more than one array. Significance level used was 0.001, and power chosen was 95% to detect a twofold change in expression. Variance of log-ratios assumed to be 0.25 and the ratio of biological variation to experimental error variation assumed to be 4 (see Dobbin and Simon, 2005)

Number of samples pooled on each array	Number of arrays required	Number of samples required
1	25	25
2	17	34
3	14	42
4	13	52

24-array experiment, one will need to use more samples in the pooled experiment. This results in a trade-off between the cost of the microarrays and the cost of sample acquisition, which is displayed in Table 4. In general, unless the samples are very available and inexpensive relative to the microarrays, pooling does not appear to be an effective way to reduce cost (Dobbin and Simon, 2005; McShane *et al*., 2003; Shih *et al*., 2004).

7. Sample size

Here we will focus on sample size determination for class comparison experiments. Sample size for prognostic studies was treated in Simon *et al*. (2002), and sample size calculations for class discovery or class prediction remain open research questions.

In class comparison problems, it is common to cycle through, gene by gene, to determine which genes are differentially expressed (although in small studies, gene variance estimates may borrow information across genes (Wright and Simon, 2003)). Although multivariate permutation tests can be more effective (Simon *et al*., 2004), it is reasonable to power the study based on multiple univariate analyses. Assuming decisions about differential expression for individual genes are based on t-test statistics, a sample size formula for a two-class class comparison experiment is $Min\left\{n : n \geq 4\sigma^2 \frac{(t_{n-2,\alpha/2}+t_{n-2,\beta})^2}{\delta^2}\right\}$, where *Min* indicates the smallest positive integer n satisfying the equation, which is found iteratively. This formula can be used either for a reference design dual-label experiment or a single-label experiment. n is the total number of arrays required, with $n/2$ for each class. σ^2 is the variance of the base 2 log-ratios for the dual-label reference design, or the variance of the base 2 log-intensities for the single-label experiment. $t_{n-2,\alpha/2}$ $t_{n-2,\beta}$ and are the $\alpha/2$ th percentile and the βth percentile of the t-distribution with $n-2$ degrees of freedom, respectively. α is the significance level of the test, and $1-\beta$ is the power to detect a difference of size δ in the class means on the base 2 log scale. Selection of an appropriate variance σ^2 is somewhat problematic because different genes are usually assumed to have different error variances, but reasonable estimates can be derived using prior data from a similar experiment (Yang and Speed, 2002).

For $n \geq 60$, the sample size formula can be based on the simpler standard normal approximation $n = 4\sigma^2 \frac{(z_{\alpha/2}+z_\beta)^2}{\delta^2}$, where $z_{\alpha/2}$ and z_β are the $\alpha/2$ th and βth percentiles of the standard normal distribution, respectively.

Sample size formulas for balanced block designs, and for experiments with technical replicates, have been presented elsewhere (Dobbin and Simon, 2005).

1. Introduction

Microarray gene expression data provide considerable challenges to statistics owing to their high-dimensional gene space and small sample size, tremendous variation in the data, and correlations among genes (*see* Article 90, **Microarrays: an overview**, Volume 4). Recognizing the analytical challenges of microarray data, researchers are seeking and developing appropriate statistical tools for data analysis. Much research effort has been drawn to this area, and publications are growing exponentially in the past several years. Supported by these analysis methods, DNA microarrays are a revolutionary high-throughput technology for biological researches, addressing a wide variety of problems such as finding or predicting subclasses of cancer (Golub *et al*., 1999; Perou *et al*., 2000; Bittner *et al*., 2000).

The measurements of interest in a microarray experiment are usually log-transformed intensities or ratios (for two-color arrays). Before statistical analysis, some data preprocessing is necessary to ensure data quality; however, for this chapter, we assume the data have been processed and are ready for analysis. One of the basic statistical questions in microarray data analysis is the identification of differentially expressed genes. Statistically, this can be viewed as a hypothesis-testing problem, and traditional parametric methods such as t-tests can be useful for simple comparisons. When distributional properties of the data are in question, nonparametric permutation methods can also be adopted to determine significant changes (Tusher *et al*., 2001; Dudoit *et al*., 2002). For more complex experimental designs including covariates, ANOVA-type models are appropriate (Kerr *et al*.,

2000; Wolfinger *et al.*, 2001; Chu *et al.*, 2002). Classification, or supervised learning, of microarray data can potentially lead to clinical diagnosis and prognosis using DNA microarray technology. The goal is to predict clinical outcomes of new samples on the basis of their gene expression profiles using classification techniques built from existing data. The ideal methods need to be robust and sensitive in prediction. To make microarray data clinically applicable, it is desirable to select a small subset of genes that predict similarly well or even better than when all genes are used. This feature-selection problem is typically a critical part of the classification problem. Finding new patterns in microarray data is another interesting problem, as it can help researchers to identify the molecular signature of diseases. Clustering, or unsupervised learning, is the primary statistical tool for this purpose (Eisen *et al.*, 1998). Clustering can be performed on both samples and genes, and can help identify subtypes of tumors and groups of genes associated with clinical outcomes (Perou *et al.*, 2000).

2. Identifying differentially expressed genes

Several basic techniques for identifying differentially expressed genes are addressed here.

2.1. T-tests

Dudoit *et al.* (2002) use a two-sample t-statistic for each gene when comparing two conditions in a microarray experiment: $t = \frac{\overline{x_2} - \overline{x_1}}{s}$, where $\overline{x_1}$ and $\overline{x_2}$ are the mean expression measure for control and test group, s is their pooled standard deviation. $s^2 = \frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}$; s_1^2 and s_2^2 are sample variances for the control and test groups, respectively. Tusher *et al.* (2001) propose the SAM (Significance Analysis of Microarrays) method (*see* Article 59, **A comparison of existing tools for ontological analysis of gene expression data**, Volume 7) that is a shrunken t-statistic $t_s = \frac{\overline{x_2} - \overline{x_1}}{s + s_0}$, where s_0 is a small inflation factor, added to stabilize the t-statistic and control false-positives for low-expression measurements. The t-statistic provides us with a relative significance of differential expression. Ordering t-statistics by their magnitude provides one way to identify the most differentially expressed genes in a list. When overall statistical significance is important, computing p-values from the t-statistics is the standard procedure. The p-values can be computed as tail areas from appropriate t-distributions or by permutation methods.

2.2. Rank-based methods

Rank-based methods only consider the order statistics of the data and make minimal distributional assumptions. They are also less sensitive to location shift and scale changes, but usually have less power than parametric methods to detect differentially expressed genes, especially as many microarray experiments have limited sample size. Park *et al.* (2001) propose a nonparametric score statistic based on Kendall's tau and assess significance through permutation of the sample class labels.

2.3. AVOVA models

When more than two treatments conditions are present in an experiment, as well as for complex experimental designs, ANOVA models are reasonable choice and provide a rigorous method for extending two-sample t-tests. Kerr *et al*. (2000) fit the ANOVA model

$$Y_{ijkg} = \mu + A_i + D_j + T_k + G_g + (AG)_{ig} + (TG)_{kg} + \varepsilon_{ijkg} \qquad (1)$$

where Y_{ijkg} is the log intensity of array i, dye j, treatment k, and gene g; μ represents the overall mean; A_i, D_j, T_k, and G_g represent array, dye, treatment, and gene main effect respectively; AG and TG give gene specific array effect and treatment effect; and ε_{ijkg} is error and assuming i.i.d. with mean zero. In the ANOVA model, the main effects A, D, T are used to account for the overall systematic effects attributable to these factors, and thus serve as normalization factors. The interaction term TG models the genes that have differential expression across treatment levels. The significance of the differences can be evaluated parametrically using t- and F-tests or nonparametrically by bootstrapping the errors ε.

2.4. Linear mixed models

Wolfinger *et al*. (2001) extend the ANOVA model by modeling array and its interaction with other effects as random effects. Random effects are typically assumed to arise from a normal distribution and allow inferences to be made on the general population from which arrays are sampled. They can also be viewed as an empirical Bayes technique. Two stages of modeling make the computations more feasible. The first stage fits the main effects not involving genes and then subtracts their estimates from the data in order to normalize them. The second modeling stage fits a separate mixed model to data for each gene and the significance of treatment effects is used as assessment of differential expression for gene g. Under this framework, other covariates can also be included in the models. One advantage of mixed model is its ability to directly estimate the variability of different random factors, such as subject and array. Chu *et al*. (2002) extend this framework to Affymetrix array data.

2.5. Multiple comparisons

Microarray experiments typically involve simultaneously testing thousands of hypotheses, and so adjusting for multiple comparisons becomes a very important issue. The common approach is to control family-wise error rate (FWER), defined as the probability of having at least one false-positive error. There are many ways to control FWER and the simplest one is Bonferroni adjustment, which divides the desired FWER by the number of tests to form a conservative significance cutoff. Holm (1979) proposes a step-down procedure to adjust p-values. For m p-values, rank p_j such that $p_{(1)} \le p_{(2)} \le \cdots \le p_{(m)}$. The step-down Holm adjusted p-values are then $p^*_{(j)} = \max_{i=1,\ldots j} \{\min[(m - i + 1)p_{(i)}, 1]\}$.

Holm's procedure is less conservative than Bonferroni procedure, and the adjusted p-values still keep the order $p^*_{(1)} \leq p^*_{(2)} \leq \cdots \leq p^*_{(m)}$. Dudoit *et al*. (2002) use Westfall and Young's (1993) step-down procedure to estimate p-values by permutation. The advantage of this procedure is that it keeps the gene–gene correlations intact and it can often outperform simpler methods.

Instead of controlling FWER, another approach is to control false discovery rate (FDR). It defines the significance level on the basis of the proportion of false rejection of null among all rejection of null. In general, controlling FDR is less conservative than controlling FWER for microarray data (Storey and Tibshirani, 2003).

3. Classification of microarray data

In general, classification starts with fitting a model $\hat{y} = f(x)$ to minimize a predefined loss function, and then using this fitted model to predict new observations. In recent years, various classification methods have been applied to microarray data, particularly in the area of cancer classification. We now describe several commonly used methods.

3.1. Nearest centroid

Define the centroid for class k as $\overline{x}_k = \sum_i^{n_k} x_{k,i}/n_k$, which is the mean vector of class k, then classify sample x to the class whose centroid is nearest. $y(x) = \arg\min_k ||x - \overline{x}_k||$. van't Veer *et al*. (2002) apply a similar method to breast cancer outcomes with correlation distance.

3.2. Shrunken centroid (PAM)

Tibshirani *et al*. (2002) propose a modified version of nearest centroid. They define a t-statistic type of score for each gene as $d = \frac{\overline{x}_k - \overline{x}}{m_k(s+s_0)}$, where $\overline{x}_k$ is the class k centroid, $\overline{x}$ is the overall centroid, s is the pooled within-class standard deviation, and s_0 is a fudge factor set to control the possible large d score when intensity is low, $m_k = \sqrt{1/n_k + 1/n}$. The idea is to shrink the d score to zero if the class centroid is very close to the overall centroid. By doing so, the class centroid will not be affected by genes too close to the overall mean (more likely to be noise). Samples are classified to the nearest shrunken centroid:

$$y(x) = \arg\min_k ||\delta_k|| \tag{2}$$

with distance defined as weighted Euclidean distance, $\delta_k = \sum_{i=1}^{p} \frac{(x_i - \overline{x}'_{ik})^2}{(s_i + s_0)^2} - 2\log \pi_k$, where $\overline{x}'_{ik}$ is the shrunken centroid for ith gene at kth class and π_k is the prior probability of class k.

3.3. *K nearest neighbor (KNN)*

KNN classification method is based on the idea that data points close to each other in the feature space neighborhood should more likely come from the same class. Therefore, by counting class labels from the k nearest neighbors, we can predict the new sample's class. Letting x_i, $i = 1, \ldots k$ be the k nearest points to the new sample x, the predicting class of x is simply the mode of $y(x_i)$. Alternatively, one can use weighted voting with weights based on the distance for classification. Dudoit *et al*. (2001) compare KNN with several other classification methods in application to several cancer microarray datasets.

3.4. *Support vector machines (SVM)*

SVM, developed in machine-learning theory (Vapnik, 1998), has been widely used in microarray classification. In contrast to other common classification methods, the dimension of SVM calculations is a function of the number of observations, not the number of predictors. Therefore, it suffers much less from the curse of dimensionality than most other methods. For a given gene expression $p \times n$ matrix X, SVM finds a hyperplane $w{\bullet}X{+}b$ that separates two classes in the input space defined by X. If the two classes cannot be completely separated with linear boundaries in the input space, we can map the input space to a higher dimension feature space $(\phi_1(X), (\phi_2(X), \ldots \; (\phi_m(X))$, where the two classes can be separated by a hyperplane $w{\bullet}\phi(X){+}b$. The actual computation involves the dot product of $\phi^T(X){\bullet}\phi(X)$, which defines a kernel function. As illustrated in Figure 1, the smallest distance between the data points in each class and the hyperplane defines the margin, and the hyperplane is found by maximizing the margin. The final classification decision only depends on the data points on the boundaries, that is,

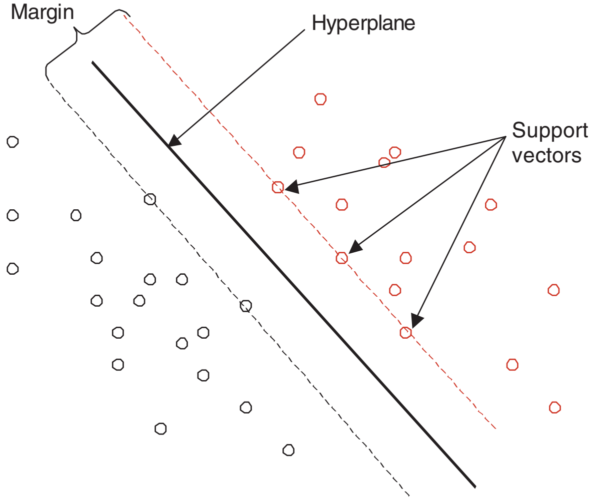

Figure 1 Illustration of SVM

the support vectors. Although SVM is developed for two-class classifications, it can be applied to multiclass problems through one-vs-other or one-vs-one algorithms (Yeang *et al*., 2001).

3.5. Neural networks (NN)

NN were developed as statistical tool for pattern recognition (Ripley, 1996). It is a two-stage classification model with a hidden layer between output Y and input data X. The hidden layer consists of M units that is a nonlinear transformation of the input X: $Z_m = s(\beta_{0m} + X\beta_m)$ with $s(x)$ serving as an activation function (usually a sigmoid function). Then Y is modeled by $g(\gamma_{0k} + Z\gamma_k)$ with $k = 1, \ldots K$ for the level of Y. The model has many weights parameters $(\beta_{0m}, \beta_m, \gamma_{0k}, \gamma_k)$, and they are learned from the training data by minimizing a loss function. Without proper regularization, a neural network can lead to overfitting problem owing to its large number of parameters. Khan *et al*. (2001) use an artificial NN to classify the small round blue cell tumor (SRBCT).

3.6. Partial least squares (PLS)

Traditional linear regression seeks a linear function of predictors X to explain as much the variation in the outcome Y as possible. The objective is achieved by minimizing the error function and obtaining least square estimate of parameters. In principal component analysis (PCA), the goal is to find a linear combination of X that accounts for the most variance in X. This is achieved through eigen-analysis. PLS balances these two objectives and finds a linear function of X that explains as much variation in both X and Y as it can. It achieves this goal by finding a linear function $t = Xw$ that maximizes its covariance with Y.

$$w = \arg\max\{Cov[t(X, w), Y]\} \tag{3}$$

The resulting PLS model can be used for predictions.

3.7. Logistic discrimination (LD)

Logistic regression models the probability of a class using a logit link function and assumes that outcomes are generated from a binomial distribution. A problem with traditional logistic regression is its limit in handling a large number of predictors. The model saturates when the number of predictors approaches the number of observations (samples). So it is difficult to directly use LD in the classification of microarray data where parameters outnumber the samples. However, LD can be used in conjunction with other dimension-reduction techniques, such as stepwise variable selection, SVD (Ghosh, 2002) and PLS (Nguyen and Rocke, 2002) for sample classification using microarray data.

3.8. *Other classification methods*

Other classification methods are also used in the literature for classification of microarray experiments. Dudoit *et al.* (2001) compare several discriminant methods for classifying several publicly available tumor datasets. Besides the KNN, they also compare Fisher Linear discriminant analysis (FLDA), quadratic linear discriminant (DLDA), classification tree (CART), bagging, and boosting. Their results showed that simple methods such as DLDA and KNN perform as good as more sophisticated methods, CART, bagging, and boosting. Golub *et al.* (1999) use a weighted voting scheme as a classifier to predict leukemia subtype AML and ALL. It is a weighted version of nearest centroid. They weight the correlation-based distance by a weight that is the Euclidean distance between the sample and the mean vector of class centroid. West *et al.* (2001) propose a Bayesian statistical regression model for the prediction of breast cancer outcome (estrogen receptor status). The model first performs an SVD to reduce the dimensionality of the data and then regresses $p(y)$ – the probability of ER positive – on the eigen genes through a probit link function, using Bayesian analysis for the model fitting. Romualdi *et al.* (2003) include recursive partition in the methods they compare.

3.9. *Criteria to evaluate classification*

The goodness of fit for a classification model is classification error rate. Without testing data, error rate is based on the prediction of training data itself. The so-called apparent error rate has significant optimistic bias. A better alternative is *cross-validation* (CV) *error* rate, where the training sample is randomly split into k roughly equal-sized groups, and for the ith group, we train the data on the other $k-1$ groups and predict the ith group. Repeat this for all k groups and estimate the error rate. In the literature, $k = n$ (leave-one-out) and $k = 10$ (10-fold) are the common choices for k. Another method for error rate estimation is bootstrap. We can bootstrap the training set and use it to predict the samples that are not in the bootstrap sample. One more advanced estimate is the ".632 estimator" (Efron, 1986).

Which method should we use? There is no universally best method in classification, and the choice of methods depends on the data, such as the number of classes, sample size, and the number of genes. SVM has shown popularity in the literature due to its overall good performance in microarray classification. Dudoit *et al.* (2001) and Romualdi *et al.* (2003) both compare several different classification methods in gene expression analysis with respect to classification performance. Dudoit *et al.* find that simple traditional methods such as LDA can perform better than the newer and more sophisticated methods. Romualdi *et al.* find through simulations that when the number of classes is less than four and sample size per group is >50, all methods perform comparably; SVM and KNN are more robust to noises in the data; LDA performs better than others when the number of classes is more than 5; and when sample size is small, NN has better performance than others. Again, these are based on simulation with a particular dimension-reduction technique and the real data are usually more complicated. It is always helpful to try several methods and compare their performance in terms of

CV error rate. Furthermore, the choice of classifiers also depends on the availability of software packages.

4. Clustering analysis

There is a large literature on clustering analysis of microarray gene expression data; Shannon *et al*. (2003) provide a good review. We here briefly discuss several commonly used methods. All methods employ some kind of distance or similarity measure; common ones include Euclidean distance and Pearson correlation. Nonparametric measures such as Spearman correlation and Kendall's tau can also be used. SAS/Proc Distance (SAS Institute Inc, 2004) describes many other alternatives. Once a distance measure has been selected, commonly used clustering methods include hierarchical clustering, K-means clustering, and self-organized maps. Model-based clustering assumes the data are from a mixture of some probability distributions.

4.1. *Hierarchical clustering (HC)*

HC is a bottom-up clustering method that starts from a distance matrix. Depending on the analysis objective, the distance can be defined between genes or samples. Let us assume we intend to cluster on genes. The HC algorithm proceeds as follows: (1) Initially, each observation forms a cluster, (2) identify the pair of clusters with the smallest distance and combine them into a new cluster, (3) update the new distance matrix, (4) repeat this process until one cluster is left. The distance matrix can be calculated by using the average distance (average linkage algorithm), the smallest distance (single linkage algorithm), or the largest distance (complete linkage algorithm) between two clusters. In practice, average linkage works quite well with standardized microarray data (Shannon *et al*., 2003). The hierarchical tree (dendrogram) resulting from HC analysis provides a very useful tool for data visualization. In combination with heat map of gene expression measures, it gives a graphical presentation of gene expression data, and is widely used by researchers. Despite its success, HC has its limitations. It is not obvious where the cutoff should be on the dendrogram to determine the number of clusters. HC can also suffer from lack of robustness, nonuniqueness, and a tendency to break large clusters. The deterministic nature of HC algorithms can result in groupings based on local decision with no opportunity to reevaluate the clustering that already is done (Tamayo *et al*., 1999).

4.2. *K-means clustering*

K-means clustering is a top-down method starting from the final required number (K) of clusters. The algorithm begins by randomly selecting K genes and defines them as the initial centroids. Then, the distances between each gene and these centroids are computed and each gene is grouped to its nearest centroid. The

centroid's position is recalculated and each gene again is regrouped to the updated nearest centroid. The iterative process continues until a prespecified convergence criterion is met. K-means clustering generates the required number of clusters and is useful when some prior knowledge of the number of clusters exists. Tavazoie *et al.* (1999) show that it is effective in analyzing microarray gene expression data on *Saccharomyces cerevisiae* with 30 clusters. Unfortunately, K is unknown in most cases. The results from K-means clustering also depend on the choice of initial centroids that are usually picked randomly. In practice, it is helpful to repeat the K-means clustering for a number of initial centroid selections and choose the best solution based on the tightness of clusters. K-means clustering is found to produce tighter clusters than hierarchical clustering (Tibshirani *et al.*, 1999).

4.3. *Self-organizing maps (SOM)*

SOM map data points from a high dimensional space to a geometrical configuration in a low dimensional space (Kohonen, 1989). The SOM algorithm starts with a simple topology, such as a grid of nodes in a two-dimensional plane and a distance function $d(N_i, N_j)$ between nodes. Each node is mapped into the original data space with a reference vector. Tamayo *et al.* (1999) and Golub *et al.* (1999) successfully apply SOMs to microarray data.

There are similarities between SOM, K-means clustering, and multidimensional scaling (Tibshirani *et al.*, 1999). Like K-means clustering, SOMs begin with the required number of clusters (nodes). Unlike K-means clustering, the positions of all nodes (not just the nearest node) are updated by each data point.

4.4. *Model-based clustering*

Unlike the above heuristic algorithms, model-based clustering algorithms start with the assumption that the data is a mixture of a finite number of distributions with a density function

$$f(x_1, \ldots, x_n) = \prod_{i=1}^{n} \sum_{k=1}^{K} \pi_k f_k(x_i | \mu_k, \Sigma_k) \tag{4}$$

where $x_i (i = 1, \ldots, n)$ is the data to be clustered on and π_k is a probability that an observation comes from component $k (k = 1, \ldots, K)$. Each component in the mixture determines a cluster, and the objective is to search for the parameters that define the components. The standard approach assumes multivariate normal distributions for f_k and utilizes EM algorithm to estimate parameters μ_k, Σ_k, and π_k. The covariance parameters (Σ_k) determine the shape of the clusters. One of the advantages of model-based clustering is that the determination of the number of clusters K becomes a model-selection problem that can be easily estimated by the well-known Akaike Information Criterion (AIC) or Bayesian Information Criterion (BIC). Another advantage of the model-based clustering is its ability to assign posterior probabilities of observations belonging to each cluster. In practice,

data transformations are often necessary to meet distributional assumptions, and requisite computations can be very intensive. Yeung *et al*. (2001b) apply model-based clustering algorithms to gene expression data.

4.5. Two-way clustering

Two-way methods cluster genes and samples simultaneously, and can identify a cluster of genes grouped with a subset of samples. Tibshirani *et al*. (1999) use a block clustering algorithm to split the data into two pieces, either in rows or in columns, whatever gives the largest reduction of total within-block variation. A similar approach based on mean square residue was introduced by Cheng and Church (2000).

4.6. Evaluation of clustering methods

Evaluating the goodness of clustering results has been an active research topic for decades. For microarray data, the best evaluation may come from the understanding of the biological processes associated with the data; however, in most cases, this is not at all possible due to the lack of full biological knowledge. Statistical evaluation can be helpful in absence of that knowledge. The first aspect of the evaluation is to determine the right number of clusters. For model-based methods, this can be solved from model selection using AIC or BIC, as discussed before. For heuristic methods, Tibshirani *et al*. (2001a) propose a gap statistic to compare a within-cluster variability measure to its expectation and choose the number of clusters on the basis of the relative size of the gap statistic and its standard deviation. Ben-Hur *et al*. (2002) determine the cluster number by a stability-based resampling approach. Good clusters are unlikely to change dramatically on the leave-one-out subsamples.

Good clusters should have relatively small variance within clusters and relatively large separations between clusters. Some scores based on these measures are developed to evaluate the quality of the clusters. The silhouette index of a cluster measures the compactness of the cluster and how far it is from the next cluster. For gene i, it is defined as

$$s(i) = \frac{b(i) - a(i)}{\max[a(i), b(i)]} \tag{5}$$

where $a(i)$ is the average distance of gene i to other genes in the same cluster, $b(i)$ is the average distance of gene i to genes in its nearest neighbor cluster. Another similar index is Dunn's index discussed by Azuaje (2002). Famili *et al*. (2004) propose a stability score to evaluate the quality of the clusters. Chen *et al*. (2002) compare several scores including silhouette in evaluating clustering performance.

Most of the methods of evaluating the quality of clustering results are based on resampling or perturbation methods. Tibshirani *et al*. (2001b) propose a prediction strength method that splits the data into a training set and a test set, and each set is

clustered separately and then assessed on how well the training set cluster centers predict the comemberships in the test set. Yeung *et al*. (2001a) introduce a figure of merit (FOM) method by predicting one sample using clusters generated from all other samples, on the basis of the idea that a good clustering scheme should have a good predictive power. Kerr and Churchill (2001) assess the stability of clustering analysis by bootstrapping the residuals from ANOVA results. Bittner *et al*. (2000) evaluate the robustness of clustering methods by adding noise to the data and compare the sensitivity of the clustering results to the level of noise. Each clustering method has its strengths and weaknesses, and the choice of a clustering method depends on the data and the analysis objective. It is helpful to have some alternative approaches to validate clustering results.

1. Gene expression data

Gene expression data characterize the absolute or relative abundance of mRNA molecules in a biological sample. Ideally, we would like to measure gene expression in some objective units, such as the number of mRNA molecules of each species that are present. In reality, this is rarely possible. Usually, the measurements are more qualitative, and even if quantitative measurements are given, the noise levels are typically rather high and often unknown. This has to be taken into account when analyzing expression data.

There are many technologies used to measure gene expression such as microarrays, serial analysis of gene expression (SAGE), RT-PCR, and northern blots. Tissue-specific gene expression may be assessed by quantification of expressed sequence tag (EST) libraries. Spatial patterns of gene expression are obtained by in situ hybridization. Of all of these technologies, microarrays are both the most high throughput and most widely used. Therefore, in this chapter, we will concentrate exclusively on the analysis of microarray gene expression data (although properly formatted data from other sources could be analyzed in a similar fashion).

To understand the rationale behind various microarray gene expression data algorithms, we need to understand some of the basic principles on which microarray technology is based. Microarrays exploit preferential binding of mRNA to their complementary nucleotide sequence. A microarray chip consists of thousands of DNA molecules attached in fixed locations onto a solid surface. The abundances of mRNA molecules in a biological sample are assessed by fluorescently labeling its mRNA extract, applying this to the microarray chip, and measuring the fluorescence intensities from each location on the array. This processed array is often called a *hybridized array*, because on this array each mRNA molecule is bound or

hybridized to its complementary DNA strand. Microarrays are often used for the comparison of two samples representing, for example, a treatment and a control, in which case the treatment and the control molecules are labeled with different dyes. Gene expression levels measured in this way are relative and expressed as ratios between the sample and control (or more commonly, their logarithms base 2).

Each individual microarray produces digital images obtained by scanning the hybridized arrays, each of which has to be transformed into a numeric representation that we call the spot quantitation matrix. In this matrix, each row represents a spot (feature) on the array, while each column represents a particular quantitation type, such as the mean of the pixel intensities in a spot. Unfortunately, the relationship between the fluorescence intensity and the abundance of a given RNA molecule is not straightforward. Moreover, some microarray technological platforms, for example Affymetrix, have specific additional data preprocessing requirements (*see* Article 57, **Low-level analysis of oligonucleotide expression arrays**, Volume 7). The data for a particular experiment consists of the collection of spot quantitation matrices for all hybridizations.

A collection of spot quantitation matrices from related hybridization experiments is the starting point for the next data transformation step. The set of spot quantitation matrices are summarized into a single gene expression data matrix, where each row represents a gene (as opposed to a feature on the array), each column represents a particular experimental condition, and each position contains one or more quantities characterizing the absolute or relative abundance of each particular gene product.

To transform fluorescence intensity measurements into relative nucleotide abundances, we have to remove systematic noise originating from a variety of sources. The transformations that correct for the systematic noise and derive the abundance measurements are known as *data normalization* (Quackenbush, 2002; Huber *et al*., 2003; Irizarry *et al*., 2003). Data normalization methods can be based either on external controls (specific control features spotted on the array in combination with control molecules added to the sample) or on various assumptions about the measurement data itself (which may or may not be reasonable for a particular experiment). One of the most common assumptions is that the total amount of nucleic acid hybridized in all the samples is equal, and this serves as the basis for widely used normalization methods such as quantile normalization, locally weighted linear regression (Lowess), and variance stabilizing normalization. External control-based normalization is necessary in some cases, particularly if we do not know how the total amount of nucleic acid changes in the sample (van de Peppel *et al*., 2003). Various software packages and tools are available for microarray data normalization, of which Bioconductor (Gentleman *et al*., 2004) is among the most popular one (*see* Article 55, **Differential expression with the Bioconductor Project**, Volume 7).

2. Extracting meaning from gene expression data

One of the first problems one faces when analyzing gene expression data matrix is the presence of missing values, that is, some of the values in the gene expression

matrix are undefined. Various methods can be used for imputing a value from the information in the existing data. These include the row average method, which uses the average expression of the gene of interest in the other samples. Other approaches that may produce more reliable estimates of missing values include weighted k-nearest neighbors (Troyanskaya *et al*., 2001), least squares, or expectation maximization (Bo *et al*., 2004).

Gene expression matrices are usually too large to enable a manual gene-by-gene study, for instance, a human microarray gene expression matrix may contain over 25 000 rows – a row per gene. Therefore, automated data analysis methods can be used to reduce the dimensionality. These methods roughly can be classified into two categories – supervised and unsupervised analysis methods (Brazma and Vilo, 2000). The two main classes of unsupervised data analyses applied to microarrays are various *clustering algorithms* and ordination-based methods such as *principal component analysis* (PCA).

3. Clustering

The rows in the gene expression data matrix are often called gene expression profiles, while the columns are called sample expression profiles. The goal of expression data clustering is to group together genes or samples that have similar expression profiles. Clustering is a well-established field, and various clustering algorithms have been invented. These include *hierarchical agglomerative clustering*, which is based on iteratively grouping together the objects that are most similar to each other, and *k-means clustering* (Hartigan, 1975), in which the number of clusters is defined a priori, and the clustering is iteratively improved by adjusting the cluster centers in Euclidean space. There are also newer clustering algorithms, such as Kohonen's self-organizing maps (Toronen *et al*., 1999; Wang *et al*., 2003), and graph-theory-based algorithms (Sharan *et al*., 2003). A simple clustering algorithm based on binning, that is, discretizing the expression profile space and clustering together the profiles that map to the same bin, has been shown to be useful for grouping data in situations in which the number of experimental conditions is relatively small (Brazma *et al*., 1998).

Before choosing a clustering algorithm, one has to define how to measure the distance between the expression profiles (Causton *et al*., 2003). Various distance measures are used, of which those based on Pearson's correlation are the most popular. Pearson's correlation quantifies the linear correlation between two expression profiles. It ranges from $+1$ to -1, where a value of $+1$ means that there is a perfect positive linear relationship between the two expression profiles (all points are on the diagonal of the scatterplot). Among popular alternatives are Euclidean distance, which takes into account the absolute expression levels, or Spearman's rank correlation, which is based on ranking the expression levels, and then measuring the correlation between the rank vectors. Some clustering algorithms are only applicable for particular distance measures, for example, k-means assumes that the distance measure has Euclidean properties.

An important consideration when selecting a clustering algorithm is its appropriateness and performance. Clustering may impose a hierarchical or flat structure on

the data, which may be built using divisive (top-down) or agglomerative (bottom-up) approaches. Divisive methods start out with the complete set of data as one large group or cluster, and proceed to add partitions that separate the objects starting with those that are most dissimilar. In the case of gene expression analysis, an object is either a gene or sample expression profile of a gene expression data matrix. *Hierarchical agglomerative clustering* is a process in which each object starts out as a separate "cluster" and these objects are successively fused, until typically all objects are included. Hierarchical agglomerative clustering starts by considering each object as a separate or singleton cluster; starting with n objects or singleton clusters, where n is equal to the total number of objects. The first iteration of clustering will group together the two objects that are most similar to form a single cluster, and leave $(n-1)$ clusters. The distances between the newly formed cluster containing two objects and all of the remaining clusters or objects are then updated and then the next most similar objects are grouped together as a single cluster. This process is carried out iteratively until there is a single large cluster, and produces a hierarchical tree (Dendrogram), as shown in Figure 1.

Hierarchical clustering was one of the first clustering algorithms applied to gene expression data (Eisen *et al*., 1998), and remains a very popular microarray analysis method. The results of hierarchical clustering are frequently represented in a hierarchical tree, also known as *dendrogram*. The branch lengths of the tree may represent the degree of similarity between the data. Note that the threshold values, that is, where to split the tree to obtain distinct clusters, have to be established independently. Usually, it is done quite arbitrarily by picking the clusters that seem either to be the "tightest", or that include genes with similar functional annotation.

Nonhierarchical, or flat, clustering groups the data into clusters, which may either be a partitioning of the data in nonoverlapping clusters or a set of overlapping clusters. The number of clusters can either be given in advance or estimated from the data by applying various criteria. The most common nonhierarchical methods are k-means clustering, self-organizing maps, and various so-called Bayesian approaches. Self-organizing maps impose a partial structure on the data, such that adjacent clusters are related. Bayesian clustering permits the incorporation of priors, that is, additional information about our knowledge of the data.

K-means is the most common method of flat partition–based clustering. It starts with the given number of cluster centers, chosen either randomly or by applying some heuristics. Next, the distance from the centroids to every object is calculated, and each object is assigned to the cluster defined by the closest centroid. Then, for each cluster a new centroid is found. The distance from each object to each of the new centroids is calculated, and in this way, the boundaries of the partitioning are revised. This is repeated until either the centroids stabilize (which is not guaranteed), or until an a priori defined maximum number of iterations have been reached. It is common that as many as 20 000 to 100 000 cycles are necessary before the position of the nodes stabilizes.

There is no compelling evidence that more sophisticated clustering algorithms perform better than the simplest ones with respect to the biological insights that have been obtained. At the same time, this does not mean that all clustering algorithms are appropriate for all datasets. It is possible that in the future, when we

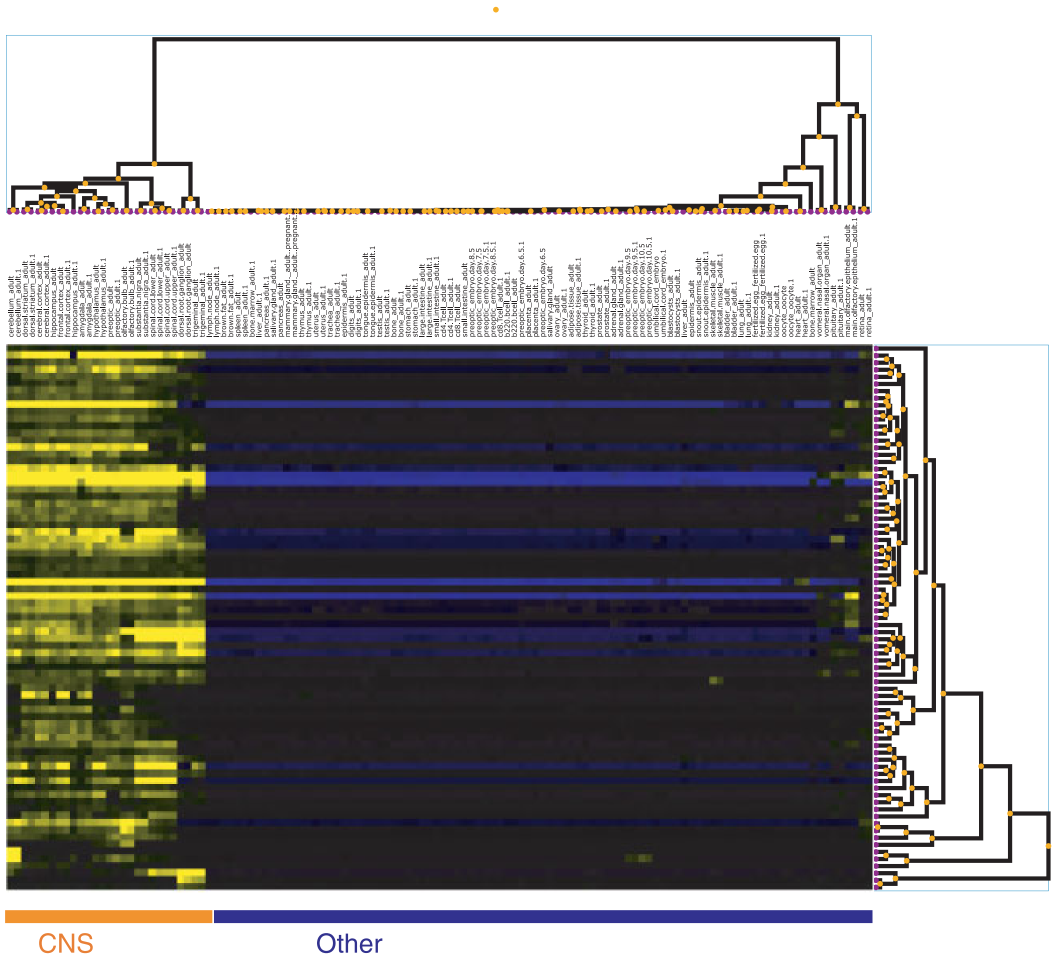

Figure 1 Hierarchical clustering of selected 77 mouse genes and 122 samples representing 61 tissue types each in two replicates (Su *et al*., 2002). The data were retrieved from ArrayExpress database (**http://www.ebi.ac.uk/arrayexpress**), accession number E-AFMX-4, and clustered and visualized using hierarchical clustering in expression profiler (**http://www.ebi.ac.uk/expressionprofiler**). Each row represents a gene and each column a sample expression profile. Genes that are overexpressed when compared to the mean expression level are in yellow, and those that are underexpressed are in blue. The genes shown were preselected using the between-group analysis component of expression profiler. These genes were the top 77 genes that discriminated most between central nervous system (CNS) and other tissue types

have a better understanding of the nature of gene expression data, more specialized algorithms will be developed that significantly outperform those now in use.

4. Ordination-based methods

Ordination is a complementary method to clustering and should not be confused with it. This is because ordination considers the variability of the whole data matrix, bringing out general gradients or trends in the data, whereas clustering investigates

pairwise distances among objects looking for fine relationships (Legendre and Legendre, 1998). Since ordination methods do not partition data into discrete clusters, they permit the detection of both gradients and discrete groupings in data. PCA and correspondence analysis (COA) are two of the many ordination methods that have been applied to microarray data analysis (Raychaudhuri *et al*., 2000; Crescenzi and Giuliani, 2001; Fellenberg *et al*., 2001).

The idea behind *PCA* and ordination is quite intuitive – if there are correlations between measured quantities, such as gene expression vectors, we can combine correlated objects and reduce the "dimensionality" of the problem. Mathematically, this means that if a linear relationship exists between gene (or sample) expression profiles in a data matrix, these can be expressed as a linear combination of the original such that colinear variables are regressed onto a new set of coordinate axes. These new axes are often called *eigenvectors*, *principal components*, *principal factors*, or *principal axes*, as they explain the principal trends in the data. These are generally ordered on the basis of their ability to explain the primary trends in the data, and the first few of these new axes (usually two or three) are used to present a dimensionally reduced representation of the data. The maximum number of new axes is equal to the number of rows or columns (whichever is smaller) of the original data matrix minus 1.

One expects coregulated (colinear) gene expression changes in response to a particular biological perturbation. For example, a microarray expression pattern "diseased" might equal x.gene1 + y.gene2 + z.gene3, where x, y, z are the loadings or contribution of each gene. Typically, there are only a few important gene trends and these are described by the first few principal components. If the study was a simple control versus treated experiment, one or two principal components might explain the major gene trends (expressed in particular tissue types). However, if the experiment was a time course, or complicated diagnosis of multiple cancer types, more principal components would be required to explain the main trends in the data. Although selection of the number of principal components is quite subjective, it can be simplified by examining the *eigenvalue* associated with each principal component. An eigenvalue scores the amount of information or variance explained by a principal component. In PCA and COA, eigenvalues are ranked from highest to lowest. Thus, the most important trends in the data (highest variance) will be described by the first few principal components.

The above described methods, clustering and ordination, do not assume that the order in which samples have been presented is important. This is not true for time-series data. Although these methods can still be applied, they will not help one to analyze order-specific properties of time-series data, such as periodicity. There are specialized methods, such as autocorrelation or Fourier analysis to perform this analysis.

After reducing thousands of profiles into a few clusters of genes exhibiting "interesting" expression behavior, a human investigator can study these genes in the context of prior knowledge to draw conclusions about the underlying biological processes and propose new experimentally testable hypotheses. Automated software tools can help in finding clusters of genes sharing the same gene annotation (Cheng *et al*., 2004; Harris *et al*., 2004), or in analyzing gene regulatory regions to identify

shared sequence patterns. Such approaches have been successful, for instance, in identifying transcription factor binding sites in yeast.

5. Supervised methods

Supervised data analysis methods exploit our prior knowledge about the genes or experimental conditions right from the beginning. For instance, if we are given a set of gene expression measurements for diseased and healthy samples, we can look for expression values in the matrix that allow the prediction of "diseased" or "normal" state of a new sample given its expression profile. This can then be used in diagnostics, but additionally, if the predictors can be described by simple rules, these can also help us in understanding the biological mechanisms of the disease. For instance, if a small subset of genes are highly expressed in the disease state and lowly expressed in normal or vice versa, these can be hypothetically implicated in the mechanisms of the particular disease. This approach has been successfully used, for instance, in cancer classification and class prediction (Hampton and Frierson, 2003).

There are a number of different techniques used in supervised gene expression data analysis, including *linear regression* or *linear discriminant analysis, nearest neighborhood analysis, support vector machines, neural networks,* and *decision trees* (Simon, 2003; Kuo *et al*., 2004). In principle, any supervised analysis or machine-learning techniques can be applied. However, it has to be noted that in gene expression analysis, the number of objects that we want to classify (samples) typically is much smaller than the number of parameters that can be used in classification (genes). This is known as the "curse of dimensionality", and is driving the development of new data analysis methods.

This problem has been most commonly circumvented by selecting subsets of genes in advance or iteratively during training. Typically, these subsets use about 50–100 genes, although it has been suggested that just a few genes might be statistically preferable (Li and Yang, 2001). Such gene selection may be cumbersome to produce, possibly involving arbitrary selection criterion, or may miss highly informative combinations of genes. To this end, Culhane *et al*. (2002) described a powerful yet simple supervised method called *between-group analysis* (BGA), a multiple discriminant approach that could be safely used when the number of genes exceeds the number of samples (Dolédec and Chessel, 1987). The basis of BGA is to ordinate the group means rather than the individual samples. For N groups (or classes of samples), we find $N-1$ eigenvectors or axes that arrange the groups so as to maximize the between-group variances (Figure 2). The individual samples are then plotted along them. Each eigenvector can be used as a discriminator to separate one of the groups from the rest. New samples are then placed on the same axes and can be classified on an axis-by-axis basis or by proximity to the group centroids. BGA was shown to be a fast and simple approach to use, yet it produced accurate discrimination as judged by the performance on gene expression test data or by a jack-knife leave-one-out cross-validation analysis (Culhane *et al*., 2002).

Frequently, in microarray studies, researchers have insufficient resources to generate adequate numbers of samples to provide a training and test dataset

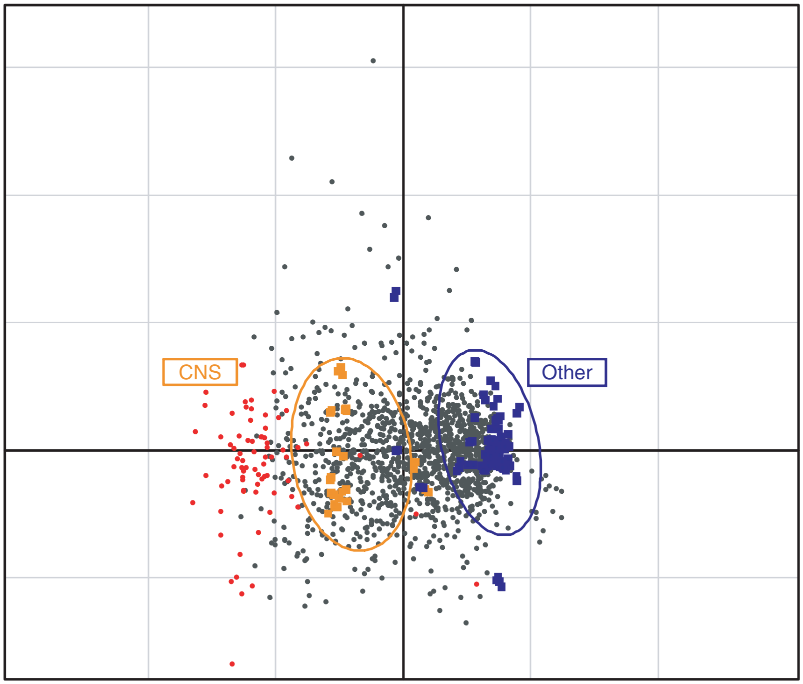

Figure 2 Visualization of two eigenvectors of a correspondence analysis of gene expression profiles of mouse tissues (Su *et al*., 2002). Correspondence analysis was performed on 1389 mouse genes and 122 samples representing 61 tissues types (as in Figure 1). These 1389 genes were the top 1389 genes that discriminated most between central nervous system (CNS) and other tissue types, as defined using the between-group analysis component of expression profiler. Genes (closed circles) and array samples (closed squares) are plotted on the one graph. A gene and array with a high association are project in the same direction from the origin. The top 77 genes (Figure 1) that discriminate between these groups are highlighted (red closed circles). The figure was obtained using the made4 package in Bioconductor. Correspondence analysis is also available in Expression Profiler

that are necessary in supervised methods such as those described above. In this case, researchers may simply rank the genes that are most differentially expressed between classes, and subsequently will use experimental approaches to validate these genes. Unfortunately, simple approaches to ranking genes are often complicated by the level of noise in the data, the low number of experimental replicates, and the high number of genes. Simple methods that rank genes using fold difference or the classical t-statistic are very susceptible to high numbers of false-positives. This has led to the development of new gene-ranking methods, of which *significance analysis of microarrays* (SAM), (Tusher *et al*., 2001) and *limma* (Smyth, 2004) are among the most popular (*see* Article 59, **A comparison of existing tools for ontological analysis of gene expression data**, Volume 7 and Article 62, **Large error models for microarray intensities**, Volume 7). SAM ranks genes using a moderated t-statistic, and the significance of these values are adjusted for multiple testing by permutation. Limma fits a linear model to the data,

but moderates the gene standard error using an empirical Bayes model to obtain a moderated t-statistic.

Automated methods can go beyond simple clustering or classification approaches. For instance, one can try to reverse-engineer the gene regulation network from gene expression data. Though it is unlikely that reverse engineering of gene regulation networks is possible purely from microarray data, nevertheless, these attempts are providing valuable insights into different properties of gene regulation networks (Schlitt and Brazma, 2002).

There exist a large number of commercial and free software tools implementing various analysis methods. Some of the most popular free software tools are Cluster and TreeView (Eisen *et al*., 1998), TIGR Multi-Experiment Viewer (Saeed *et al*., 2003), J-Express (Dysvik and Jonassen, 2001), and Bioconductor (Dudoit *et al*., 2003). Expression Profiler (Kapushesky *et al*., 2004), which is provided by the European Bioinformatics Institute, is available from **www.ebi.ac.uk/expressionprofiler** and is an on-line-based microarray data analysis tool that implements many of the methods described above. To use this tool, the user only needs a web browser.

6. Meta-analysis

Microarray experiments are relatively expensive, but they generate data that can continue producing new knowledge long after the experiments have been completed. Large, systematic, high-quality datasets are proving to be a valuable resource for the research community, similar in value to genome sequence data. Meta-analysis of large expression datasets, particularly when combined with other relevant datasets, and analyzed using new methods, may bring new insights that go beyond the scope of the original studies. Simple methods, such as *coinertia analysis*, can be used to compare the global correlation between gene expression profiles of the same tissues or cell lines obtained in different studies, even if these studies have used arrays with different catalogs and numbers of genes (Culhane *et al*., 2003). Much information can be obtained by comparing gene profiles across studies or even between species. For instance, the comparison of the expression profiles of homologous genes across a range of organisms can help in predicting the orthologous genes (Grigoryev *et al*., 2004), or comparing similar processes, such as the cell cycle or other core biological processes in different organisms (Stuart *et al*., 2003). To make such gene expression data meta-analysis possible, it is important that all the experimental details and sample properties are recorded. *Minimum Information About a Microarray Experiment* or MIAME is a microarray data annotation standard developed by the Microarray Gene Expression Data Society for this purpose (Brazma *et al*., 2001).

Several public repositories have been established to collect the publicly available microarray data – *Gene Expression Omnibus* at the NCBI, *CIBEX* in DDBJ, and *ArrayExpress* at the European Bioinformatics Institute (Brazma *et al*., 2003). A researcher can query these databases for all experiments of a given type for a given organism and retrieve the respective data, which then can be combined with the researcher's own data, or used for designing new experiments. With growing

amounts of microarray data, improving quality, and new analysis methods being developed, such databases are becoming an essential resource for functional and comparative genomics research.

1. Introduction

The measurement of transcriptional activity in living cells is of fundamental importance in many fields of research, from basic biology to the study of complex diseases such as cancer. DNA microarrays provide an instrument for measuring the mRNA abundance of tens of thousands of genes. Currently, the measurements are based on mRNA from samples of hundreds to millions of cells, thus expression estimates provide an ensemble average of a possibly heterogeneous population. Comparisons within gene across sample are supported by the current state of the technology, whereas comparisons within samples and between genes are not. In this article, we focus on detecting probes that reflect differences in gene expression associated with specific phenotypes of samples. The Bioconductor Project (**http://www.bioconductor.org**) provides a variety of tools for this purpose. We will illustrate general principles of the analysis, rather than discussing detailed features of individual software packages; for this, we refer the reader to the Bioconductor website and the *vignettes* provided with each of the packages.

Gene expression is a well-coordinated system and hence measurements on different genes are, in general, not independent. Given a more complete knowledge of the specific interactions and transcriptional controls, it is plausible, and likely, that more precise comparisons between samples can be made by considering the joint distribution of specific sets of genes. However, the high dimension of gene expression space prohibits a comprehensive exploration, while the fact that our understanding of biological systems is only in its infancy means that we do not know which relationships are important and should be studied. Practitioners have adopted two different strategies to deal with this situation. One ignores the dependencies and treats each gene as a separate and independent experiment, while

the other strategy attempts to use relevant biological knowledge to reduce the set of genes to a manageable number.

The first strategy ignores the dependencies between genes and analyses the data gene-by-gene, for example, through statistically testing for association between each gene's expression levels and the phenotypic data. This approach has been popular, largely because it is relatively straightforward and a standard repertoire of methods can be applied. However, the approach has a number of drawbacks: most important is the fact that a large number of hypothesis tests will be carried out. This involves a problematic trade-off between specificity and sensitivity. p-value correction methods provide one mechanism for redress, by focusing on specificity, but they are not a panacea, as the price will usually be a large loss in sensitivity.

The second approach is to reduce the number of hypotheses to a more manageable number that directly address the questions of biological interest. Ideas such as nonspecific filtering also fall under this rubric. But the main tool here is the use of prior biological knowledge to focus on a small number of genes and of their associations with each other. Specific examples include examining particular pathways or specific transcription factors (looking for downstream correlates) that have been associated with a disease or condition of interest.

We note that it does not have to be an either-or world. It is entirely possible, and acceptable, to first test specific hypotheses of interest and to then adopt a more exploratory approach as a basis for the next round of experimentation and hypothesis testing.

Carrying out these explorations requires the use of software analysis tools. There are very many different projects and commercial enterprises that provide software solutions. Many of the gene-expression analysis tools present themselves as a graphical user interface to a predefined set of operations on the data. Such systems are easy to use and provided that they incorporate the methodology that the user wants, they perform satisfactorily. In contrast, the Bioconductor project provides an extensible and flexible set of tools that are associated with a full-fledged programming language that has a large collection of numerical and statistical libraries. While more difficult to use, the software is also much more powerful and can accommodate virtually any chosen analysis.

Bioconductor is an international open source and open development software project for the analysis and comprehension of genomic data. Its main engine is *R* (Gentleman and Ihaka, 1996), a language and environment for statistical computing and graphics (**http://www.r-project.org**). The software runs on all major computing platforms, Unix/Linux, Windows, and Mac OS X. Through its flexible data-handling capabilities and well-documented application programming interface (API), it is easy to link it to other applications, such as databases, web servers, numerical or visualization software. *R* and Bioconductor support the concept of *compendiums* (Gentleman and Temple Lang, 2004), which are interactive documents that bundle primary data, processing methods (computational code), derived data, and statistical output with the textual documentation and conclusions.

2. Gene selection

Fundamental to the task of analyzing gene expression data is the need to select those genes whose patterns of expression are related to a specific phenotype of interest. This problem is hampered by the issues mentioned above, in that we would prefer to model the joint distribution of gene expression but the biological knowledge is lacking and instead genes will be treated as independent experiments. In this section, we describe some of the analysis strategies that are in widespread use. Since our own bias is to reduce the set of genes under consideration to those that we consider to be expressed in a substantial subset of the population we will first prefilter the genes using a nonspecific approach (i.e., we do not use phenotypic information to aid in our decision). In addition to a short description of nonspecific filtering, we consider several different testing paradigms.

One popular approach is to simply conduct a standard statistical test, such as the t-test, for each gene separately. As Kendziorski *et al*. (2003) indicate, analyses that treat genes as separate, independent experiments tend to be less efficient than those that adopt a Bayesian approach in order to take advantage of the shared information between genes. Baldi and Long (2001), Tusher *et al*. (2001), Lönnstedt and Speed (2002), Smyth (2004) proposed moderated versions of the t-statistic where the gene-specific variance estimator in the denominator is augmented by a constant that is obtained from the data of all genes. This is especially useful when few replicated samples are available and typically gene-specific variance estimates are highly variable. The moderated t-statistics may be seen as interpolations between a fold-change criterion and the usual t-statistic. Except for the variant of Tusher *et al*. (2001), they coincide with the latter in the case of many replicates. Irrespective of the number of replicates, the use of a fold-change criterion may be beneficial, as this helps to screen out genes whose effect sizes are small in absolute terms, even though they may be statistically significant.

To demonstrate some of the differences between these general approaches, we consider expression data from 79 samples from patients with acute lymphoblastic leukemia (ALL) that were investigated using HGU95AV2 Affymetrix GeneChip arrays (Chiaretti *et al*., 2004). The data were normalized using quantile normalization, and expression estimates were computed using RMA (Irizarry *et al*., 2003). There are a lot of different choices for the preprocessing. This can have much impact on the results of subsequent analyses (Huber *et al*., 2002). The appropriate choice of method depends on the technology and experimental design, and this is still a subject of active research. Here, we sidestep these issues and instead focus on the expression values themselves.

Of particular interest is the comparison of samples with the BCR/ABL fusion gene resulting from a chromosomal translocation (9;22) with samples that are cytogenetically normal. There are 37 BCR/ABL samples and 42 normal samples (labeled NEG).

We will demonstrate some aspects of differential gene expression analysis with this example data set. Code chunks using functionality from *R* and Bioconductor illustrate the calculations.

2.1. Nonspecific filtering

This technique has as its premise the removal of genes that are deemed to be not expressed according to some specific criterion that is under the control of the user. One may also want to eliminate from consideration the genes that do not show sufficient variation in expression across all samples, as they tend to provide little discriminatory power. Many of the genes represented by the 12 625 probe sets on the array are not expressed in B-cell lymphocytes (either in their normal condition or in any of the disease states being considered), which are the cells that were measured in this experiment, and hence the probes for those genes can, and should, be removed from the analysis. In the example below, we require estimated intensities to be above 100 fluorescence units in at least 25% of the samples, and the interquartile range (IQR) across the samples on the log base 2 scale to be at least 0.5. We start with an object, `eset`, that contains the expression data and the phenotypic information for the samples.

```
> library(genefilter)
> f1 <- pOverA(0.25, log2(100))
> f2 <- function(x) (IQR(x) > 0.5)
> ff <- filterfun(f1, f2)
> selected <- genefilter(eset, ff)
> sum(selected)

[1] 2391

> esetSub <- eset[selected, ]
```

The following analysis will be based on the expression data of the 2391 selected probe sets.

2.2. Differential expression – one gene at a time

We now turn our attention to the process of selecting interesting genes by using a statistical test and treating each gene as an independent experiment. Our setting is the simple case where we compare two phenotypes, the BCR/ABL-positive and the cytogenetically normal samples. Many of the principles of the analysis presented below are also valid in the case of a more general response variable, or in a multifactorial experiment. We concentrate on the differences between the *mean* expression levels in the two groups. In other analyses, different properties of the distributions of the expression levels could also be interesting. For instance, Pepe *et al*. (2003) look at the ability of any given gene to serve as a marker for one of the groups, meaning that high (or low) expression of the gene is mainly seen in this group.

Using the *multtest* package, we perform a permutation test for equality of the mean expression levels of each of the 2391 selected genes.

```
> cl <- as.numeric(esetSub$mol == "BCR/ABL")
> resT <- mt.maxT(exprs(esetSub), classlabel = cl, B = 1e+05)
```

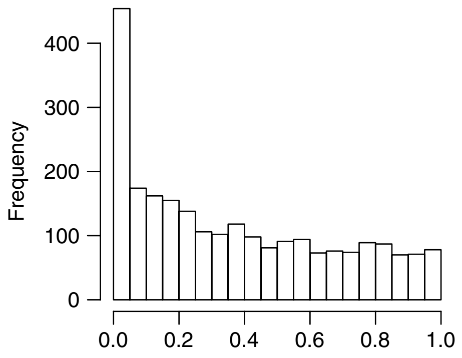

Figure 1 Histogram of *p*-values for the gene-by-gene comparison between BCR/ABL positive and negative leukemias

```
> ord <- order(resT$index)
> rawp <- resT$rawp[ord]
> names(rawp) <- geneNames(esetSub)
```

The histogram of *p*-values (Figure 1) suggests that a substantial fraction of the genes are differentially expressed between the two groups.

In order to control the family-wise error rate (FWER), that is, the probability of at least one false-positive in the set of significant genes, we use the permutation-based maxT-procedure (Westfall and Young, 1993). We obtain 18 genes with an adjusted *p*-value below 0.05. Compare this number to the size of the leftmost bar in the histogram – clearly we are missing out on a large number of differentially expressed genes.

Looking at the description of the probe sets with smallest adjusted *p*-values, we see that the three most significant ones represent the ABL1 gene, which, in the form of the BCR/ABL fusion gene, defines one of the phenotypes we are studying.

```
1636_g_at 39730_at  1635_at  40202_at  37027_at
    "ABL1"     "ABL1"    "ABL1"     "BTEB1"     "AHNAK"
```

As illustrated above, the FWER is a very stringent criterion, and in some microarray studies, only few genes may be significant in this sense, even if many more are truly differentially expressed. A more flexible criterion is provided by the false discovery rate (FDR), that is, the expected proportion of false-positives among the genes that are called significant. We use the procedure of (Benjamini and Hochberg, 1995) as implemented in *multtest* to control the FDR at a level of 0.05, which leaves us with 109 significant genes (note however that this procedure makes certain assumptions on the dependence structure between genes):

```
> res <- mt.rawp2adjp(rawp, proc = "BH")
> sum(res$adjp[, "BH"] < 0.05)

[1] 109
```

2.3. Multiple probe sets per gene

The annotation package *hgu95av2* provides information about the genes represented on the array, including LocusLink identifiers (**http://www.ncbi.nlm.nih.gov/LocusLink**), Unigene cluster identifiers, gene names, chromosomal location, Gene Ontology classification, and pathway associations. While the term *gene* has many aspects and can mean different things to different people, we operationalize it by identifying it with entries in the LocusLink database. One problem that does arise is that some genes are represented by multiple probe sets on the chip. The multiplicities for the HGU95AV2 chip are shown in the following table.

```
Multiplicity            1    2    3   4    5    6    7    8    9
No. LocusLink IDs    6719 1579  505 121   29   18   10    9    1
```

This leads to a number of complications, as we discuss in the following. Of the 2272 LocusLink IDs that have more than one probe set identified with them, we found that in 510 cases our nonspecific filtering step of Section (2.1) selected some, but not all corresponding probe sets.

In Section (2.2), we found that the three top-scoring probe sets all represented the ABL1 gene. However, there are five more probe sets on the chip that also represent the ABL1 gene, none of which passed our filtering step from Section (2.1). The permutation p-values of all eight probe sets are:

```
  1635_at   1636_g_at  39730_at  1656_s_at   32974_at
  0.00001     0.00001   0.00001    0.05800    0.23000
32975_g_at  2041_i_at 2040_s_at
    0.53000     0.59000   0.76000
```

Some caution must be used in interpreting this particular example. The BCR/ABL-positive samples have an mRNA that is the fusion of the BCR gene and the ABL1 gene, and this fused gene is generally highly expressed. The heterogeneity in the p-values listed might be due to the specific location of the probes in the ABL1 gene and whether or not they are able to detect the fused gene. This question could be further investigated using the *hgu95av2probe* package from Bioconductor, which contains information about the probe sequences and their location.

Figure 2 shows a comparison of the t-statistics calculated in Section (2.2) between 206 *pairs* of probe sets that represent the same gene. While in many cases they are approximately concordant, there are a number of cases where a *significant* p-value would be obtained for one of the probe sets but not for the other.

The consistency of the behavior of different probe sets that are intended to represent the same gene is seldom systematically reported. Here, we found some striking discrepancies. How can these be interpreted? In some cases, different probe sets may represent alternative transcripts of the same gene, which could be expressed differently. However, the magnitude of the problem suggests that

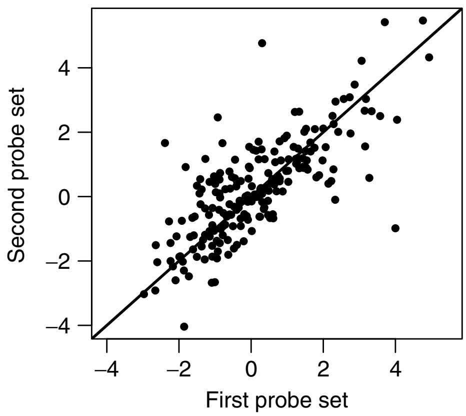

Figure 2 Comparison between the t-statistics for pairs of probe sets that represent the same gene

there may also be errors in the mapping of the probes to LocusLink records. A better understanding of the set of all possible transcripts and their mapping to the genome, but also further and better quality control procedures are needed.

2.4. *The relation between prefiltering and multiple testing*

As explained above, the aim of nonspecific filtering is to remove genes that, for example, because of their low overall intensity or variability, are unlikely to carry information about the phenotypes under investigation. The researcher will be interested in keeping the number of tests/genes as low as possible while keeping the interesting genes in the selected subset.

If the truly differentially expressed genes are overrepresented among those selected in the filtering step, the FDR associated with a certain threshold of the test statistic will be lowered due to the filtering. This appears plausible for two commonly used global filtering criteria: *Intensity-based filtering* aims to remove genes that are not expressed at all in the samples studied, and these cannot be differentially expressed. Concerning the *variability across samples*, a higher overall variance of the differentially expressed genes may be expected, because their between-class variance adds to their within-class variance.

To investigate these presumed effects, we compare the scores for intensity and variability that we used in the beginning for gene selection with the absolute values of the t-statistic, which we now compute for all 12 625 genes.

```
> IQRs <- esApply(eset, 1, IQR)
> intensityscore <- esApply(eset, 1, function(x)
   quantile(x, 0.75))
> abs.t <- abs(mt.teststat(exprs(eset), classlabel=cl))
```

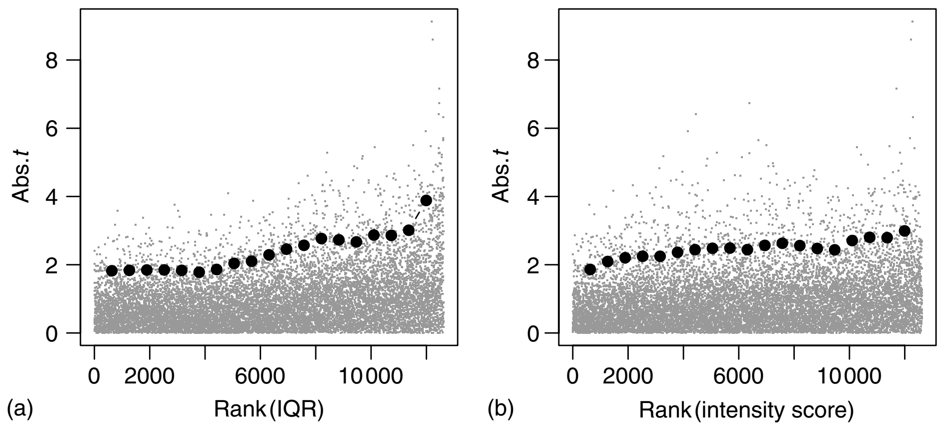

Figure 3 Plots of the absolute values of the t-statistic (y-axis) against the ranks of the values of the two filtering criteria: (a) interquartile range (IQR), (b) an overall intensity score. The larger dark dots indicate the 95%-quantiles of the absolute value of the t-statistic computed for moving windows along the x-axis

The result is shown in Figure 3. Gene selection by the interquartile range (IQR) seems to lead to a higher concentration of differentially expressed genes, whereas for the intensity-based criterion, the effect is less pronounced.

2.5. *Moderated t-statistics*

Many microarray experiments involve only few replicated samples, which makes it difficult to estimate the gene-specific variances that are used, for example, in the t-test. In the *limma* package, an Empirical Bayes approach is implemented that employs a global variance estimator s_0^2 computed on the basis of all genes' variances. The resulting test statistic is a moderated t-statistic, where instead of the single-gene estimated variances s_g^2, a weighted average of s_g^2 and s_0^2 is used. Under certain parametric assumptions, this test statistic can be shown to follow a t-distribution under the null hypothesis with the degrees of freedom determined by the data (Smyth, 2004).

With 79 samples at hand, there is no big difference between the ordinary and the moderated t-statistic. Here we use the ALL data to illustrate the behavior of the different approaches for small sample sizes: We repeatedly draw random small sets of arrays from each of the two groups and apply different statistics for differential expression. The results are compared to those of the analysis of the whole data set. As an approximation, we declare the 109 genes with an FDR below 0.05, based on the whole set of samples, as truly differentially expressed genes.

```
> is.diff <- res$adjp[order(res$index), "BH"] < 0.05
```

Now we consider a random subset of four arrays per group and compute ordinary as well as moderated t-statistics for them.

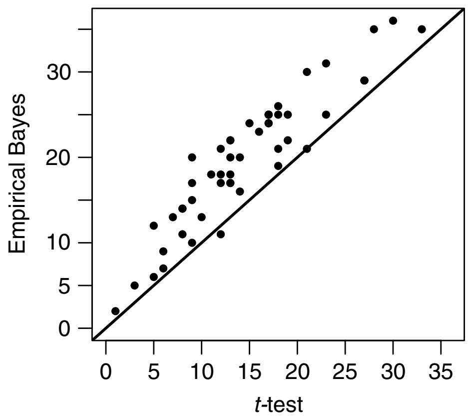

Figure 4 Number of true-positives among the top 100 genes selected by the t-test (x-axis) and a test based on a moderated t-statistic, as implemented in the *limma* package (y-axis)

```
> groupsize <- 4
> design <- cbind(c(1, 1, 1, 1, 1, 1, 1, 1), c(0, 0, 0, 0, 1, 1,
+ 1, 1))
> g1 <- sample(which(esetSub$mol== "NEG"), groupsize)
> g2 <- sample(which(esetSub$mol== "BCR/ABL"), groupsize)
> subset <- c(g1, g2)
> fit <- lm.series(exprs(esetSub)[, subset], design)
> eb <- ebayes(fit)
> tsub <- mt.teststat(exprs(esetSub)[, subset], classlabel=cl[subset],
    +test = "t.equalvar")
> rawpsub <- 2 * (1 - pt(abs(tsub), df=2 * groupsize - 2))
```

For a comparison, we define true-positives as those genes that are among the 100 most significant ones in the tests based on the small data set, and which were also selected in the analysis of the full data set.

```
> TPeb <- sum(is.diff[order(eb$p.value[, 2])[1:100]])
> TPtt <- sum(is.diff[order(rawpsub)[1:100]])
```

Repeating this procedure for 50 random subsets of arrays, we then compare the numbers of true-positives between the two methods. The results are shown in Figure 4.

It appears that for small sample sizes, the moderated t-statistic, which may be seen as an interpolation between the t-statistic and a fold-change criterion, has a higher power than the simple t-test.

3. Asking specific questions – using metadata

We now turn our attention to analyses that are based on asking more specific and detailed questions that relate directly to the known biology of the system or disease

under study. We examine three different biological aspects. First, we ask whether differentially expressed genes are enriched on specific chromosomes.

3.1. Chromosomal location

In the following, we look at all genes with an unadjusted $p < 0.01$ (taking the median p-value in the case of several probe sets per gene), and conduct a Fisher test for each chromosome to see whether there are disproportionally many differentially expressed genes on the given chromosome. The information on the chromosomal location of genes is taken from the annotation package *hgu95av2*.

```
> ll <- getLL(geneNames(esetSub), "hgu95av2")
> chr <- getCHR(geneNames(esetSub), "hgu95av2")
> names(chr) <- names(rawp) <- NULL
> chromosomes <- unique(chr[!is.na(chr)])
> ll.pval <- exp(tapply(log(rawp), ll, median))
> ll.chr <- tapply(chr, ll, unique)
> ll.diff <- ll.pval < 0.1

> p.chr <- sapply(chromosomes, function(x) {
+      fisher.test(factor(ll.chr == x), as.factor(ll.diff))$p.value
+ })

> signif(sort(p.chr), 2)

      7      17       X      15       8      21       Y       3
 0.0062 0.1100 0.1800 0.1800 0.2000 0.2900 0.3300 0.3600
      6      22       4      12       5       9       1      10
 0.4400 0.4800 0.5600 0.5900 0.6100 0.6700 0.6900 0.6900
      2      16      18      20      11      19      14      13
 0.7000 0.8200 0.8300 0.8700 0.9100 0.9200 1.0000 1.0000
```

We identify chromosome 7 as being of potential interest. Out of the 87 genes that are mapped there, 35 were differentially expressed according to our criterion. We further explore this by visualizing gene expression on Chromosome 7. In Figure 5, we present the output of the `plotChr` function from the *geneplotter* package. In this plot, gene expression values for each sample are separated according to the strand of the chromosome that the gene is located on. Then a lowess smoother is applied (across genes, within sample) and the resultant smooth estimate is plotted. The top part of the plot represents the positive strand, while the bottom part of the plot represents genes on the negative strand. High expression values are near the outside of the plotting region, while low expression values correspond to the center (i.e., the expression values are mirrored). One can readily detect regions of heterogeneity between samples (such as the left end of both strands and again around `38299_at` on the negative strand).

3.2. Using Gene Ontology data

A second source of valuable biological data that is easily accessible through Bioconductor software is data from the Gene Ontology (GO). It is known that

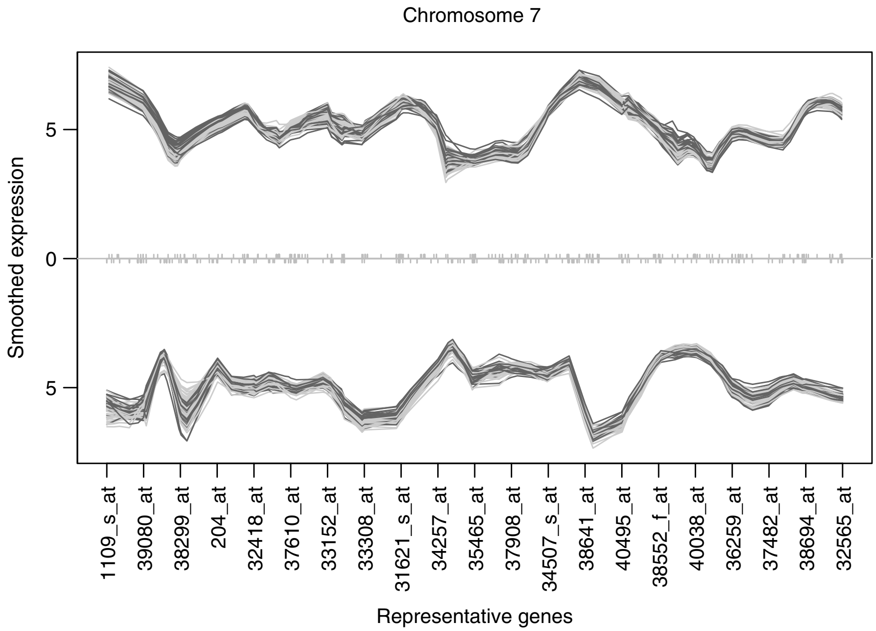

Figure 5 Smoothed expression for chromosome 7, both strands are plotted separately

many of the effects due the BCR/ABL translocation are mediated by tyrosine kinase activity. It will therefore be of interest to examine genes that are known to have tyrosine kinase activity. We examine the set of GO terms and identify the term, `GO:0004713` from the *molecular function* portion of the GO hierarchy as referring to `protein-tyrosine kinase activity`. We can then obtain all Affymetrix probes that are annotated at that node, either directly or by inheritance, using the following command.

```
> tykin <- unique(lookUp("GO:0004713", "hgu95av2", "GO2ALLPROBES"))
```

We see that 234 probe sets are annotated at this particular term. Of these, only 41 were selected by the nonspecific filtering step of Section (2.1). We focus our attention on these probes and repeat the permutation t-test analysis of Section (2.2).

In the analysis of the GO-filtered data, seven probe sets have FWER-adjusted p-values less than 0.1. They are printed below, together with the adjusted p-values from the first analysis that involved 2391 genes.

```
[1] "GO analysis"

   1635_at  1636_g_at  39730_at  40480_s_at  2039_s_at
   0.00001     0.00001   0.00001     0.00002    0.00030
   36643_at  2057_g_at
    0.02383    0.08282
```

```
[1] "All Genes"

   1635_at  1636_g_at  39730_at  40480_s_at  2039_s_at
   0.00001     0.00001   0.00001     0.00095    0.01407
   36643_at    2057_g_at
    0.46938      0.82884
```

Owing to the reduced number of tests in the analysis focused on tyrosin kinases, we are left with more significant genes after correcting for multiple testing. For instance, the probe set `36643_at`, which corresponds to the gene DDR1, was not significant in the unfocused analysis, but would be if instead the investigation was oriented toward studying tyrosine kinases.

3.3. *Using pathways*

In a closely related disease, chronic myeloid leukemia, there is evidence of a BCR/ABL-induced loss of adhesion to fibronectin and the marrow stroma. This observation suggests that there may be substantial differences between the BCR/ABL samples and the NEG samples with respect to the expression of genes involved in the integrin-mediated cell adhesion pathway. A version of this pathway was obtained from the Kyoto Encyclopedia of Genes and Genomes (KEGG) as Pathway 04510. The relevant genes were identified and mapped to the corresponding Affymetrix identifiers using the *hgu95av2* and *KEGG* packages from the Bioconductor Project.

There were 110 probes that correspond to 67 LocusLink identifiers. Now we can ask whether any of these are differentially expressed between the two groups. Users can either apply our nonspecific filter first, or not, depending on their particular point of view.

We did not apply the nonspecific filtering of Section (2.1) and simply applied the `mt.maxT` function to obtain permutation adjusted p-values for differences between the BCR/ABL and the NEG group. This analysis identified four probe sets that had significant p-values. Three corresponded to FYN and one to CAV1. To compare with the other analyses reported above, we determined that there were four probe sets included on the HGU95AV2 chip for FYN and of these three were selected by the nonspecific filtering in Section (2.1) and the same three were selected here. In Section (2.2), we found two of the three FYN probes had significant p-values, after adjustment. On the other hand, CAV1 is represented by a single probe set and it was not selected in Section (2.1) because it was expressed at levels above 100 in only nine samples.

A scatterplot matrix of the gene expression data for the four selected probes is presented in Figure 6. This plot provides corroboration for some of some of the points made previously about probe set fidelity. For two of the FYN probe sets, the agreement is remarkably good. But their correlation with the third set of FYN measurements is poorer. We can also see that CAV1 expression is related to the BCR/ABL phenotype, but does not seem to be related to FYN expression.

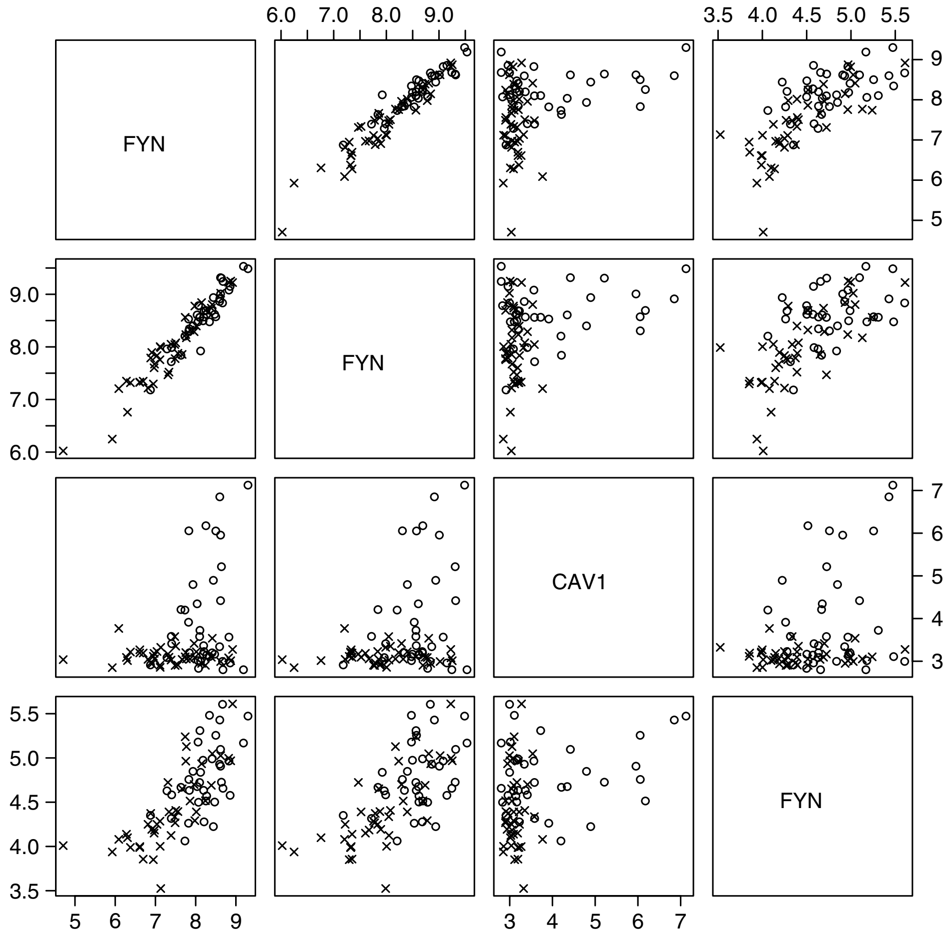

Figure 6 Pairwise scatterplots of the expression values for the four probe sets selected. Crosses indicate BCR/ABL negative samples, circles denote BCR/ABL positive samples

4. Discussion

Understanding the complex dependencies between the transcriptional activities of genes remains an important, difficult, and essentially unsolved problem. Current analysis of differential gene expression mostly works on a gene-by-gene basis, where the necessary concepts are within reach and established statistical tests can be used. Statisticians have directed a lot of attention to methods for p-value correction. This has led to widespread adoption of these methods and particularly of the false discovery rate (FDR). They rely on the assumption that those tests with the most extreme p-values are most likely to have arisen from hypotheses that are truly false. The decision boundary is shifted sufficiently to ensure that some required proportion of those hypotheses deemed false are in fact truly false. But such an approach cannot be viewed as a solution to the real problem of identifying all

truly false hypotheses. We note that in adjusting the rejection boundary, one has also taken an unknown number of truly false hypotheses and deemed them to be true. Furthermore, there is no guarantee that the biologically most relevant genes are the ones with the most extreme p-values. Genome-wide expression profiles may be dominated by secondary changes in gene expression, such that the primary effectors may be buried within long lists of statistically significant genes. There is no simple fix to this problem apart from testing fewer and more directed hypotheses and where possible this should be done.

In the examples of Section (3), we demonstrated a variety of analyses incorporating biological information that are currently available and easily carried out. We showed that such analyses have the capability of extracting more information from the data than an omnibus approach can. Increases in our understanding of the relevant biology coupled with gains in statistical knowledge will likely lead to even more promising analyses.

Acknowledgments

We are grateful to Drs. J. Ritz and S. Chiaretti of the DFCI for graciously providing their data. And also, to the developers of *R* and those of the Bioconductor software packages that have made it possible to so easily consider a wide variety of approaches to analyzing these data.

Specialist Review

Mass spectrometric data mining for protein sequences

Christian Cole, Patrick J. Lester and Simon J. Hubbard
University of Manchester, Manchester, UK

1. Introduction

The ability to study genes and their protein products on a genome-wide basis is driving a paradigm shift in modern biology from hypothesis-driven to more predictive, hypothesis-generating bioscience, where the state of every gene and/or gene product in different biological conditions can potentially be studied. Driven by complete genome sequences, proteomics is one example of these techniques, which offers a key advantage over many other postgenomic functional studies in that the proteome is predominantly the functional entity in a cell or tissue. Proteins are responsible for carrying out most biological functions and, therefore, also for dysfunction and disease. Hence, proteins are frequently targeted for treatment in the form of drugs and therapeutics. Proteomic data sets can provide both qualitative and quantitative information on proteins, potentially thousands of different proteins expressed in a cell or tissue. At the heart of proteomics lies advances in mass spectrometry (see Volume 3, Section 1) and protein/peptide separation (*see* Article 2, **Sample preparation for proteomics**, Volume 5) along with, crucially, attendant bioinformatics tools. Whether the proteomics experiment is qualitative or quantitative, protein species must at some stage be identified by bioinformatics tools from mass spectra derived from the proteins themselves, or more commonly from their peptides or peptide fragment ions. This technique exploits the knowledge of the exact masses of the amino acid constituents of protein sequences along with the growing data banks of protein sequences against which the mass spectral information may be compared to match peptides (and thereby their "parent" proteins).

In this review, we discuss the data mining approaches being taken to identify proteins from characteristic mass spectra, and recent advances in both experimental and bioinformatic approaches, focusing on the two principal application areas of peptide mass fingerprinting (PMF) and tandem mass spectrometry (MS/MS). Both are widely used to identify proteome proteins from mass spectra, although MS/MS approaches can deliver protein sequence information directly. Tandem MS

permits the sequence of a peptide (and by extension, protein) to be determined *de novo* in some cases so that the protein sequence does not need to be known *a priori*. This is of particular importance when the sequence of the genome in question is not currently available or there is a difference between the real and "virtual" proteome; that is, when proteins are posttranslationally modified leading to different isoforms that are not predicted directly from the genome sequence. Indeed, when a complete genome sequence is unavailable, this leads to the problem of cross-species protein identification where sequence information is of particular importance. We also examine this issue and review approaches to cross-species proteomics, as well as current developments in tandem MS peptide database searching.

2. Mass spectrometry in proteomics

In order to appreciate how protein sequences can be studied via mass spectrometry, the basic techniques are presented here and discussed in more detail elsewhere (see Volume 3, Section 1). In using mass spectrometry for proteomics, "soft ionization" techniques are exploited whereby the analyte, usually proteolytic peptide fragments of a protein or mixture of proteins, is introduced into the instrument as a solution for electrospray ionization (ESI) (*see* Article 14, **Sample preparation for MALDI and electrospray**, Volume 5), or as a solid dissolved in a UV-absorbing crystalline matrix for matrix-assisted laser desorption/ionization (MALDI) (*see* Article 14, **Sample preparation for MALDI and electrospray**, Volume 5). The gaseous ions generated are separated by their mass-to-charge ratios (m/z) in a mass analyzer and then detected by either an electron multiplier or multichannel plate detector. This occurs on a microsecond timescale, allowing the whole process to be automated and, therefore, facilitates high-throughput analysis of many samples, yielding m/z measurements for each of the analyte ions. The masses of the proteolytic peptides (usually generated via tryptic digestion) can then be used to search protein sequence databases in order to determine the most likely protein(s) that could have generated the equivalent peptide masses; a technique usually referred to as peptide mass fingerprinting (PMF).

Mass spectrometry can also be used for peptide/protein sequencing via tandem MS. In this instance, collision-induced dissociation (CID) is used to initiate fragmentation of the protein/peptide. Here, the so-called precursor ions are selected for in an initial mass-to-charge (m/z) ratio measurement. This precursor ion is then subjected to fragmentation where some of the kinetic energy is converted into internal energy through collisions with gaseous atoms (e.g., Argon), causing the molecule to fragment. The m/z of the subsequent fragment ions, referred to as the fragment ion series, are then measured and with this information, the sequence of the precursor ion can be inferred. Other fragmentation techniques can be employed that will generate an alternative fragment ion series, from that generated in CID, of the peptide. The information obtained from the fragment ion spectra can either be annotated or used directly to search for the peptide sequence that produced it in a sequence database.

3. Data mining using PMF

3.1. Same-species protein identification

PMF remains the method of choice for single-protein identification in many laboratories as it can easily be automated into a successful high-throughput protein identification strategy compared to the more elaborate tandem MS approaches (Wilke *et al*., 2003). The basic problem is to determine which protein(s) has produced the set of proteolytic peptide ions obtained by mass spectrometry. Typically, proteins are first separated by two-dimensional polyacrylamide gel electrophoresis (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5). The resultant protein "spots" are digested with a proteolytic enzyme, usually trypsin, and the resulting peptides are extracted from the gel and analyzed on the mass spectrometer. A bioinformatic search tool then uses the experimentally derived primary (peptide ion *m/z* values) and secondary protein information to search sequence databases for an entry that best correlates with the experimental *m/z* data within a given experimental error. Ideally, the list of results will enable the user to identify the experimental protein with high confidence.

Confident protein identification by PMF broadly depends on the number of experimental proteolytic peptides that match theoretical database peptides calculated using the same cleavage specificity within the experimental error tolerance. Early algorithms ranked proteins on the basis of the total number of matches for each database entry (Mann *et al*., 1993). This relied on high-quality experimental data, and often failed to accurately discriminate between random matches from large database proteins and true-positive hits. Unambiguous identification was generally assumed for database proteins with five matching peptides, a sequence coverage of approximately 15% and a gap between the potential "true-positive" and next best "false-positive" match. However, more recent algorithms such as MOWSE/Mascot (Pappin *et al*., 1993; Perkins *et al*., 1999), ProFound (Zhang and Chait, 2000), PeptIdent2 (Gras *et al*., 1999), and MS-Fit (Clauser *et al*., 1999) typically use sophisticated scoring systems to distinguish true-positive from false-positive matches, improving upon simple ranking on the number of peptide matches (Eriksson *et al*., 2000).

Mascot incorporates probability-based scoring, extending the MOWSE algorithm (Pappin *et al*., 1993), which also forms the basis for MS-Fit (Clauser *et al*., 1999). This algorithm accounts for the dependency on protein mass of the peptide mass distributions in the database, effectively down-weighting random matches to larger database proteins. The algorithm calculates a probability that the protein match is nonrandom, which is then converted into a Mascot score by a log transform. Another popular PMF search engine, ProFound (Zhang and Chait, 2000), uses a scoring algorithm based on Bayesian probability theory to identify a specific protein in a database from its attendant peptide masses. ProFound differs from Mascot in that it calculates a probability that each protein in the database is the correct match, assuming that the true protein *is* in the database, ranking candidate matches in decreasing likelihood. ProFound also attempts to reduce the bias toward random matches of larger proteins by introducing a specific term in the scoring function and, importantly, also models the experimental error in *m/z*

determinations. Unlike Mascot, ProFound assumes that matching peptides from the true protein will be normally distributed about the theoretical database peptide mass with a standard deviation proportional to the experimentally determined mass error. Conversely, Mascot gives equal weighting to any match within the error tolerance supplied by the user. It is unclear whether these provide universal advantages or disadvantages to protein identification for PMF. For all algorithms, other background information (species of origin, molecular mass of the intact protein, enzyme cleavage chemistry, etc.) can be included and additional empirical peptide information can be submitted when available, such as limited sequence information with MS-Tag (Clauser *et al*., 1999). This background information is either explicitly or implicitly modeled by the scoring system through appropriate choice of search parameters.

A distinct advantage of the Mascot and ProFound algorithms is the significance testing that allows users to assign confidence to their hits. Extending MOWSE into a probabilistic frame allows Mascot to determine a threshold at the 5% significance level, and the software provides a simple color-coded histogram showing nonrandom protein matches above this limit. ProFound supplies significance testing via expectation values calculated from raw probability scores, based on the distribution of random scores, providing e-values in much the same way as a BLAST search (Altschul *et al*., 1997). In this case, the number of expected protein matches with such a score is returned, depending on the database searched.

Independent of algorithm choice, confident matches are often subject to user opinion, especially when several sequences return a score indicating a confident match. This can be due to database redundancy or error, or several species in the database yielding random noise from protein homologs. The objective assessment of database search results to determine the probability that the identified protein is a false-positive has been investigated (Eriksson *et al*., 2000) and remains of significant importance with the emphasis on high-throughput studies. A recent comparison of PMF algorithms (Chamrad *et al*., 2004) examines some key points comparing the algorithms, finding that Mascot and ProFound outperform MS-Fit, although they both have advantages for some proteins. Although all the algorithms attempt to account for scoring bias from high-mass proteins, an apparent bias toward large proteins was observed in identifications from ProFound and MS-Fit, but not Mascot. In addition, the same group has developed a meta-score approach based on the three algorithms, which offers some advantages (Chamrad *et al*., 2003) and appears to be a successful "consensus" strategy that has worked well in other areas of bioinformatics such as secondary structure prediction. Again, an independent significance score in the form of an expectation value is provided and appears to outperform the independent PMF algorithms.

3.2. Cross-species protein identification

Although genome-sequencing projects continue apace, there will always remain unsequenced species owing to the incredible diversity of life on this planet. The cross-species protein identification problem, where homologous (and ideally, *orthologous*) proteins should be identified from experimental data, is particularly

acute for PMF-based strategies. In this case, even a single amino acid substitution can radically alter the mass of a peptide preventing a match to orthologous peptides (and adding noise by creating a match to random, unrelated peptides). Despite this, several approaches have proven successful in cross-species PMF recently, as has been recently reviewed (Lester and Hubbard, 2002; Liska and Shevchenko, 2003a). Generally, approaches have required the use of more than just proteolytic peptide mass data as this is generally poorly conserved across species barriers (Wilkins and Williams, 1997; Lester and Hubbard, 2002). Instead, features such as amino acid composition, protein mass, and isoelectric focusing point (pI) were much better conserved, and attempts to combine these and other protein and peptide features have shown some limited success (Cordwell *et al*., 1997; Wilkins *et al*., 1998). However, this requires a comprehensive amino acid analysis of the protein in question, which is not as amenable to high-throughput studies as PMF. Some groups have described successful cross-species protein identification strategies using PMF, including marsupial proteins using a mammalian database and MultIdent (Verrills *et al*., 2000) and the characterization of *Ochrobactrum anthropi* proteins using amino acid composition and/or peptide mass fingerprinting (Wasinger *et al*., 1999). In addition to this, peptides corresponding to functionally important (conserved) motifs have been used in order to identify similar patterns in phylogenetically distant organisms (Cordwell *et al*., 1997). The authors suggest that sequences sharing above 60% sequence identity may be identified using PMF via homologous proteins and a ± 6-Da peptide mass tolerance, although this yields many false-positives. Other recent approaches have focused on high mass–accuracy determinations of peptide masses, in the range ± 0.5–5 ppm, where it is possible to reduce the number of candidate proteins to a tractable number so that single amino acid substitutions may be incorporated into the search (Clauser *et al*., 1999). Hence, coupled with high-accuracy peptide mass measurements, homologous proteins with 70% sequence identity or better can be matched with confidence. Indeed, an approximate cutoff of 70% sequence identity has been suggested by several groups as a limit beyond which cross-species PMF becomes impossible without detailed sequence information (Cordwell *et al*., 1997; Clauser *et al*., 1999) despite a considerable enrichment above random of tryptic peptide conservation even at lower identity levels (Lester and Hubbard, 2002).

When partial genomic sequence information is available, then several approaches have proven successful, relying on preliminary, unannotated genome sequences and related resources such as expressed sequence tags (ESTs) (Choudhary *et al*., 2001; Lisacek *et al*., 2001; Kwon *et al*., 2003). A recent study devised an approach to search raw genome sequences directly with PMF data, termed genome fingerprint scanning (GFS), which does not require annotation of coding regions or open reading frames (Giddings *et al*., 2003). Instead, an *in silico* digest of the whole genome is performed in all six reading frames and peptide ions matched via their *m/z* values to the putative "genomic" tryptic peptides. Genomic regions where a high density of such matches are found are then examined and an algorithm scores each sequence window according to the number of in-frame hits, consistency of frame assignment, missed cleavages, and abutment of fragments. The algorithm performs comparably to standard PMF tools but offers advantages over protein

database searches since GSF can spot unannotated proteins and cope with some limited sequencing/frameshift errors. Given the success of tandem MS, however, this approach remains the one that would normally be applied only when others fail.

EST databases, typically available prior to completion of genome sequences, are targeted toward protein coding sequences, represent the majority of all sequence entries in Genbank, and can be obtained at a fraction of the cost of a whole-genome sequence. However, they are problematic for PMF approaches since they are usually only 500–600 nucleotides in length and do not contain the whole protein sequence. One study has circumnavigated this problem by checking for consistency of EST matches in six reading frames across "contig" sequences derived from assembly of overlapping EST sequences, ensuring that matches are in the same reading frame, and using BLASTX (Altschul *et al*., 1997) homology searches to correctly identify likely peptides (Lisacek *et al*., 2001). Many EST contigs will contain alternatively spliced forms, and careful analysis of the data allows these biologically important protein variants to be identified, which would not otherwise be evident from a translated genome sequence.

4. Data mining using tandem MS

Although PMF remains the most amenable method for automated, high-throughput proteomics for most laboratories, tandem MS approaches are catching up rapidly and offer a number of advantages particularly for cross-species and *de novo* studies. The rise of tandem MS methodologies has aided protein identification by giving a partial or complete peptide sequence for searching against a database (Eng *et al*., 1994; Mann and Wilm, 1994). This additional information on a peptide, in conjunction with its *m/z*, narrows down the list of possible correct matches, and can be obtained from a variety of instruments including ESI triple quadrupole, MALDI-QTOF (quadrupole time-of-flight), ion-trapping, and Fourier Transform Ion Coupled Resonance (FT-ICR) instruments, often coupled with a liquid chromatography stage to aid the separation of complex samples (Aebersold and Mann, 2003; *see also* Article 5, **FT-ICR**, Volume 5, Article 7, **Time-of-flight mass spectrometry**, Volume 5, Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5, and Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5). The latter is used widely with ion-trapping instruments in the Multidimensional Protein Identification Technology (MudPIT) pioneered by Yates (Washburn *et al*., 2001; *see also* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5).

The added information available from tandem experiments generates its own set of bioinformatic challenges. Unless performing *de novo* peptide sequencing, the added sequence information generated by tandem MS requires that the database must contain peptide sequences under study in addition to its mass, as is the sole requirement for PMF. In principle, a BLAST (Altschul *et al*., 1997) or FASTA-type (Pearson and Lipman, 1988) sequence search filtered for the peptides of the right mass would rapidly give a list of possible matches. However, tandem results are rarely that precise in their description of a peptide's sequence, often containing

ambiguities such as uncertainty due to isobaric residues (Ile/Leu and Gln/Lys) or modifications (e.g., acetylation is equivalent to a change from Ser to Glu) (Creasy and Cottrell, 2002; Chamrad *et al*., 2004). Often, the peptide sequence information is limited to only a few C- or N-terminal residues, with the majority of the sequence still unknown (Mann and Wilm, 1994). Additionally, the protein/peptide sequence in a database may not be an exact match to that determined in the MS/MS experiment, due to misannotation, database errors, existence of multiple isoforms and/or paralogs in the database.

Although direct annotation/interpretation of MS/MS peptide spectra rarely determines the complete amino acid sequence, there is frequently sufficient data, coupled with the precursor ion *m/z*, to determine the peptide from a protein sequence database. Indeed, modern software tools facilitate automatic database searches using uninterpreted spectra along with constraints on the precursor ion *m/z* range at which the first mass spectrometer was "gated" (Eng *et al*., 1994; Perkins *et al*., 1999; Field *et al*., 2002). Some systems permit real-time searching in a complex LC-MS/MS run, or the database searching may be performed off-line.

There are many algorithms for mining MS/MS data for peptide/protein sequences. Of these, the two most widely used are Mascot (Perkins *et al*., 1999; Creasy and Cottrell, 2002) and SEQUEST (Eng *et al*., 1994; Yates *et al*., 1996). As mentioned for PMF searching, Mascot uses a probability-based scoring system to match database sequences to the search data. The algorithm is able to integrate probability scores from both PMF (i.e., peptide *m/z* matches) and MS/MS (i.e., peptide fragment ion *m/z* matches) searches to derive an overall probability of matching a given protein. The score calculated is the chance of the protein match being obtained at random. The significance of this probability score is then readily apparent, and Mascot reports hits above a 5% significance level as confident matches. SEQUEST uses a cross-correlation algorithm that compares the 200 most abundant experimental spectral peaks for the search peptide with proteolytic peptide ion fragment spectra generated *in silico*. The algorithm searches the top 500 database peptides that match the parent ion's mass (within a set tolerance) and then calculates a cross-correlation score (X_{corr}) between the processed experimental spectrum and the reconstructed database spectra.

Although SEQUEST does not have a significance score, as is the case with Mascot, it is claimed that if the difference in score (ΔC_n) between the first and second ranked hits is <0.1, then it is likely that the top hit is a false-positive (Yates *et al*., 1996). Despite this, in a recent paper comparing the relative performance of the two algorithms, on the basis of standard search parameters, SEQUEST was found to separate true-positives from false-positives "more obviously" than Mascot (Chamrad *et al*., 2004). Mascot's scoring system was found to be more sensitive to changes in the search parameters than SEQUEST, but overall, the initial results were not greatly improved upon. The single most effective change for improving protein matching was to reduce the database from all species to just mouse, the species of interest. Apart from improving the number of correct matches, reducing the size of the database also improves on the search speed. However, the downside is that with a reduced database the chances of a random hit are increased owing to deterioration in score separation between random and nonrandom hits, suggesting

that there is a compromise between specificity and sensitivity when altering search parameters.

Although Mascot's significance testing provides a measure of confidence in the database match obtained with the search data, this does not mean, however, that a top match that is not above the 5% significance score is necessarily an incorrect match. However, significance testing is widely valued by users, and the popularity of the SEQUEST algorithm has led to the development of a statistical framework for the assessment of peptide and attendant protein matches derived from SEQUEST hits (Keller *et al*., 2002; Nesvizhskii *et al*., 2003). In the first of these studies, expectation maximization is used to obtain parameters for a discriminant function F that is used to classify SEQUEST peptide identifications as either correct or incorrect. The algorithm is trained on a set of known peptide identifications from 18 known mammalian proteins, and also incorporates knowledge of the number of tryptic termini and considers doubly and triply charged precursor ions. This approach can increase the number of correct SEQUEST identifications by up to 46%. Building upon this, a Bayesian framework is constructed using the same data and bacterial decoy proteins to provide probability estimates for individual proteins being correctly identified. The algorithm considers both the number of sibling peptides confidently identified in an LC-MS run for each protein, as well as degenerate peptides present in multiple proteins in the database, and can offer high sensitivity (94%+) at low error rates (1.2%), frequently correctly identifying low abundance, low molecular weight proteins from only a single peptide match. Approaches such as these are critical for the high-throughput LC-MS/MS experiments where manual confirmation of thousands of protein and peptide matches is impractical.

Other algorithms tend to be similar in their approaches. MS-Tag/MOWSE (Pappin *et al*., 1993; Clauser *et al*., 1999), PepFrag (Fenyö *et al*., 1998), and PepSea (Mann and Wilm, 1994) use fragment ion data in combination with the parent ion *m/z* to generate a list of potential peptides to search against a database using homology-based search strategy. An advantage of this approach is that it is error-tolerant and thus will match similar sequences. However, it is also worth noting that error-tolerant tandem MS searches are possible directly with the latest version of Mascot (Creasy and Cottrell, 2002). Newer methods such as Sonar (Field *et al*., 2002) and Tandem (Craig and Beavis, 2003) concentrate on the speed of searching as well as accuracy of matching. Sonar has the additional advantage of being able to search genomic as well as proteomic databases. Sonar employs a scoring system based on "peptidic vectors" derived from the experimental and database peptides, and correct matches are predicted on the dot-product of the vectors. The resultant scores are cast into an expectation value framework derived from a set of simulations that leads to e-values that are assigned to each peptide, and ultimately protein, match (Field *et al*., 2002).

Recent studies have seen several new algorithms being developed. The Tandem algorithm exploits some of the features of SONAR as well as other algorithms and scoring systems and word-searching methods of BLAST to speed up tandem MS database searching (Craig and Beavis, 2003). PEP_PROBE (Sadygov and Yates, 2003) uses a hypergeometric probabilistic distribution model to improve the scoring of peptide matches to a database, assuming that fragment ion frequencies follow a

hypergeometric distribution, and thus the probability of a random match must also follow this distribution. Another recent algorithm, ProbID (Zhang *et al*., 2002), also uses a novel probabilistic model for the ranking of tandem MS data, which performs similarly to SEQUEST, but its significance testing seems to differentiate well between similar matches. Although these algorithms promise advances in methodology, they still need to be fully validated and compared to current methods to see their full utility.

4.1. JEDI approaches

Although tandem MS approaches can generate extensive sequence information, it is not always necessary or possible to generate a complete (albeit with ambiguities) sequence for a tryptic peptide. PMF is already a powerful technique in identifying proteins from their peptide masses alone, but the additional knowledge of even the presence of a single amino acid in a peptide can improve database searching significantly; theoretically, 83% of all *Saccharomyces cerevisiae* and 79% of all *Caenorhabditis elegans* proteins could be identified from a single aspartate-containing peptide (Sullivan *et al*., 2001), and partial sequence information via a "peptide sequence tag" frequently permits unambiguous protein identification from a single peptide match (Mann and Wilm, 1994). These limited sequence approaches have been labeled the JEDI approach (Just Enough Diagnostic Information) and demonstrate the power of protein identification from directed, promoted fragmentation pathways using a variety of derivatization chemistries (Brancia *et al*., 2001; Sidhu *et al*., 2001; Sullivan *et al*., 2001; Karty *et al*., 2002). This is especially useful when high-quality MS/MS data is not available due to low abundance or weak signal of the precursor ion, and fragmentation of the precursor in a controlled fashion yields a small number of detectable daughter ions rather than comprehensive but weak (or undetectable) daughter ions.

5. *De novo* peptide sequencing

Tandem MS is capable of capturing sufficient information to determine a proteolytic or other peptide sequence, sometimes in its entirety, without recourse to a database search. This is usually referred to as *de novo* peptide (or even, protein) sequencing. This is of particular use where the species of interest does not have a completed genome sequence, or the peptides/proteins in question are not represented in the known databases. Although fewer computational approaches have been developed compared to those that attempt to "look up" the peptide from a known database, several tools exist (Taylor and Johnson, 1997; Dancik *et al*., 1999; Chen *et al*., 2001), as reviewed recently by Standing (2003). The LUTEFISK algorithm uses a sequence graph derived from a filtered set of peaks from a fragment ion spectrum to construct lists of likely matching peptide sequences, which are in turn searched against a protein database with a modified version of the FASTA algorithm (Taylor and Johnson, 2001). The SHERANGA algorithm also uses a spectral graph to denote a peptide sequence, using peaks as nodes and *m/z* and edges or vertices

corresponding to mass differences of a single amino acid (Dancik *et al*., 1999). The algorithm then uses methods from graph theory to find the highest scoring paths through the graph, representing a list of candidate peptide sequences. In this case, no database sequences are required at all, and the algorithm can be considered to be truly *de novo*. A related approach (Chen *et al*., 2001) uses dynamic programming to traverse a spectral graph to find the optimal path and, hence, the most likely peptide sequence.

As mentioned, the *de novo* sequencing problem is particularly acute for cross-species peptide identification when no database sequence is available. Shevchenko and colleagues have extended the *de novo* approach with tandem data, including that from post source decay MS, to identify peptides across species (Shevchenko *et al*., 2001; Liska and Shevchenko, 2003b). Their MS-BLAST algorithm adapts standard BLAST searching to interrogate a protein database using predicted peptide sequences from tandem MS data, adapting the scoring system to cope with isobaric residues and tryptic sites to successfully identify canine peptides without their presence in the database.

6. Data archival

As with all high-throughput and data-intensive technologies, the storage, dissemination, and analysis of the resultant information becomes a real challenge. Fortunately, in proteomics, this has not been forgotten and several proposals have been published or put forward on how best to deal with this aspect of proteomics. The Proteomics Standards Initiative (PSI) (Orchard *et al*., 2004) has been set up and is in the process of defining an International data standard based on different approaches such as PEDRo (Taylor *et al*., 2003), ProDB (Wilke *et al*., 2003), PARIS (Wang *et al*., 2004), RADARS (Field *et al*., 2002), and others (Jones *et al*., 2003). The goal is to define a complete, robust and distributable standard for the publication of proteomics data (*see* Article 61, **Data standardization and the HUPO proteomics standards initiative**, Volume 7). At present, data standards are emerging and latest developments are best viewed on the PSI website (**http://psidev.sourceforge.net/**).

7. Future directions

Although there have been many interesting developments in the field of data mining for proteome proteins and peptides, there is still some way to go in this area. It is still widely acknowledged that current software approaches are still not really robust enough for high-throughput studies, and many peptide MS/MS spectra still do not produce confident identifications. There are many reasons why a tandem MS spectrum does not lead to a confident peptide/protein identification, but improvements can surely be made from a better fundamental understanding of gas-phase peptide ion chemistry. A recent study has applied statistical tests to improve this situation using a large database of peptide spectra, and reexamining the mobile proton theory for peptide fragmentation (Kapp *et al*., 2003). This builds on previous studies from Wysocki, Yates, and colleagues (Breci *et al*., 2003) who

have found similar trends in fragmentation pathways in tryptic peptides promoted by the presence of particular amino acid combinations in the amino acid sequence. Approaches such as these promise to improve peptide MS/MS interpretation and identification algorithms when this information can be incorporated.

Alternatively, developments in mass spectrometry itself could outstrip the bioinformatics, using "top-down" approaches available from Electron Capture Dissociation (ECD) and FT-ICR instruments (*see* Article 5, **FT-ICR**, Volume 5). Here, the protein ion itself is introduced into the mass spectrometer and fragmentation is induced via ECD, yielding peptide ions series from which sequence information can be inferred (Horn *et al*., 2000). Although this technique promises much, it is still far away from the routine analyses available to most labs or the high-throughput required for a comprehensive proteome map required by some labs.

Short Specialist Review

Low-level analysis of oligonucleotide expression arrays

Xuemin Fang and **Wing Hung Wong**
Harvard School of Public Health, Boston, MA, USA

Cheng Li
Dana-Farber Cancer Institute, Boston, MA, USA

1. Oligonucleotide expression microarrays

Affymetrix GeneChip® oligonucleotide expression microarrays are manufactured through a combination of photolithography and combinatorial chemistry (**http://www.affymetrix.com/technology/manufacturing/index.affx**). GeneChip® technology produces arrays with hundreds of thousands of different probes at an extremely high density, so that researchers could generate high-quality genome-wide data using small sample volumes. The features of an oligonucleotide array are represented by the probe sets. There are usually 8000–20 000 probe sets on a single array, depending on the array type. A probe set has 11–20 probe pairs (usually 16 for U95 arrays and 11 for U133 arrays), and a probe pair consists of one perfect match probe (PM) and a mismatch probe (MM), and both PM and MM probes are oligonucleotides of 25 bp. Each probe set is designed for one target gene; the PM probes have exactly the same complementary sequences with the segments of the cRNA of the target gene, and MM probes are the same as the paired PM probes, except for the middle base (13th), which is replaced by a single-base substitution.

2. Image analysis and feature extraction

In microarray experiments, arrays are hybridized to the prepared solution of sample cRNA, in which each probe hybridizes to the cRNA of its target gene, which is labeled with a fluorescent dye. After hybridization, intensity values are read from a laser scanner. To extract the features from the image intensities, the Affymetrix Microarray Suite software (MAS) first determines the preset feature boundaries and then uses a dynamic gridding algorithm to segment the image and then compute

the feature intensities using a percentile algorithm (Lockhart *et al*., 1996). Schadt *et al*., (2000, 2001) also developed an adaptive image processing algorithm that analyzes the distribution of pixel intensities for a given feature, computes the feature intensities, and estimates the blurring effects. In the presence of the image artifact, the MAS software allows users to manually mask out the problematic features; however, the process could be time-consuming. Schadt *et al*. (2000) proposed a semiautomatic way to mask out the problem regions.

3. Presence calling

An advantage of oligonucleotide array over cDNA array is that with the PM and MM intensities, it is possible to determine whether a gene is expressed in the sample or not. Affymetrix determines the presence of a gene by calculating a set of statistics (Lockhart *et al*., 1996) to estimate the parameters of a presence or absence decision tree. Schadt *et al*. (2000) determine the presence of a gene by testing for each pair of PM and MM intensities, if PM and MM are equal in distribution; and if the ratio of PM/MM is equal to the MM/PM in distribution. Liu *et al*. (2002) present a detection call algorithm based on Wilcoxon's signed-rank test by calculating the discrimination scores.

4. Normalization

When multiple arrays are used in an experiment, array intensities may not be directly comparable. One batch of arrays may be brighter or dimmer than another batch; arrays processed by one technician may be brighter or dimmer than that processed by another technician. This raises the issue of how to normalize the arrays so that the differences due to the technical factors are eliminated while the biologically differential expression patterns are still retained. Normalization can have a profound influence in determining differentially expressed genes and other subsequent high-level analysis (Hoffmann, 2002).

The MAS suite uses a simple scaling of the expression indexes (see Section 6) to normalize between the arrays, by making the trimmed average expression of each array to be a prespecified value, for example, 250. Other methods normalize at the probe level: Li and Wong (2001b) normalize arrays to a baseline array according to a running-median, smoothing curves fitted through a set of iteratively selected rank-invariant probes; Bolstad *et al*. (2003) normalize arrays by making the distribution (or quantiles) of probe intensities for each array in a set of arrays the same. Åstrand (2003) first imposes an orthogonal change of basis of the log intensity matrix, then fits a curve between the two arrays and transforms the array to be normalized, changes back to the original basis and scale according to the curve.

These normalization methods assume that the arrays to be normalized together do not have a large number of differentially expressed genes. When normalizing arrays of different sample or tissue groups, one solution is to normalize within groups separately so that the biologically meaningful differential expression patterns are preserved after normalization; Another solution is to normalize according to a set

of housekeeping genes (genes known to have a constant expression regardless of tissue types) (Hill *et al*., 2001; Baugh *et al*., 2001); also, in the newer Affymetrix array types, there are 100 control housekeeping probe sets for the purpose of normalization or quality assessment.

5. Background adjustment

Array intensity background can come from physical and biological sources (Naef *et al*., 2001): physically, the light reflection of the substrate, or the photo detector dark current can affect the array intensities. Biologically, the nonspecific cross-hybridization of the probes to the nontarget genes also adds up to the observed probe intensities and thus obscure the real intensity signal generated by the hybridization of the probes to their target genes.

How to estimate the background, especially the biological background? Is the background an additive effect? Is it probe-specific or the same for the probe set or even the whole array? How do we take advantage of the MM probe intensities? MM probes are intended to serve as the nonspecific hybridization background control of the probe pair, by assuming that the specific binding of MM probe to the target gene is greatly reduced because of the middle-base substitution, and the observed MM intensity is mostly due to the nonspecific cross-hybridization, whose magnitude does not differ significantly from the nonspecific cross-hybridization of its paired PM probe. Then if we subtract the MM intensity from the PM intensity, the remaining part should be due to the real hybridization intensity signal of the PM probe to its target gene. By utilizing this quantity, we hope to derive an expression index that reflects the target gene's expression level in the sample solution. This is the basic idea that motivates the Affymetrix MAS 4.0 algorithm and the dChip PM/MM difference model (Li and Wong, 2001a).

In reality both PM and MM, probes hybridize to their target gene as well as to various nontarget genes, which greatly complicates the situation. Researchers have made efforts to estimate the background: some estimate the distribution of the background by estimating the mean and stand deviation of the MM intensities (Naef *et al*., 2001; Irizarry *et al*., 2003b); some estimate the biological background by modeling the cross-hybridization parameter (Affymetrix Workshop, 2003). Affymetrix MAS 5.0 software uses MM to construct a robust estimate of the probe-specific background (Hubbell *et al*., 2002).

6. Expression index

An expression index is a numeric value to reflect the gene's cRNA concentration based on the observed intensities. The ultimate goal of probe-level analysis of the oligonucleotide array is to extract the expression index from the entangled information we have: PM intensities, MM intensities, background, and cross-hybridization. Most expression index calculation methods estimate and adjust cross-hybridization intensities during the background adjustment step (see Section 5). After the adjustment, the remaining probe intensities are assumed to be purely due

to the hybridization of the probes to their target gene. MAS 4.0 or 5.0 estimate the expression index by taking the average or robust average of the PM and MM intensity differences. The Model-based Expression Index (MBEI) (Li and Wong, 2001a) uses a multiplicative model of gene expression index and the probe sensitivity index to fit the background-adjusted intensities with several varieties: LWF (Li Wong Full Model) fits both PM and MM intensities, LWR (Li Wong Reduced Model) fits the PM and MM differences, and PM-only model fits the PM intensities. All of them are implemented in the dChip (Li and Wong, 2003). This model-based approach attaches standard errors to the estimated expression indexes and probe sensitivity indexes for assessing array and probe quality. The Robust Multichip Average (RMA) (Irizarry *et al*., 2003b) fits the log-transformed, background-subtracted PM probe intensities with a linear additive model, including an array effect and a probe effect.

With the recently available probe sequence information, researchers are able to go deeper in index estimation and probe selection. It has been found that the probe intensity depends on the physical properties of the probe and its target gene. (Hekstra *et al*., 2003) use a Langmuir adsorption model to reflect the sequence dependence of the probe hybridization and the chemical saturation, and estimate the gene's absolute mRNA concentration in picomolar. Zhang *et al*. (2003) use the probe sequences to model the binding interaction and measure expression after estimating the nonspecific binding. Held *et al*. (2003) construct a model using hybridization rate equations, calculated free energies and microarray data for known target concentration to estimate the gene concentration. Wu *et al*., 2004 improve array background adjustment with probe sequence information, and use an empirically motivated stochastic model to compliment the physical model for estimating expression index (Wu and Irizarry, 2004).

Mei *et al*. (2003) makes an effort in probe selection by designing a probe response metric with a thermodynamic hybridization model.

7. Comparison of different methods

How to choose one set of normalization, background adjustment, and expression index method to analyze one's data? Cope *et al*. (2004) have developed an assessment tool (AffyComp website, 2003) for Affymetrix probe-level expression measures. Various aspects related to accuracy and precision, and from a biological perspective (James *et al*., 2004), were assessed using two standard datasets: the Affymetrix spike-in dataset and the GeneLogic dilution dataset (can be downloaded from the AffyComp website). This assessment tool is available on the Web and has generated comparison results for a number of submitted methods. Knowing the pros and cons of each method helps to decide which one you may want to use. In a brief comparison of Affymetrix MAS software, dChip, and RMA, Irizarry *et al*. (2003a) pointed out that compared to MAS, both RMA and dChip add a slight bias to the expression index while reducing much more variance. Features of each software or method are also of interest to the users in making the decision. For example, dChip has a friendly user interface for the biologists, while Bioconductor has access to many statistical functions so prototype analysis can be carried out easily. Other

comparisons of the expression indexes are done by some other researchers (Lemon *et al*., 2002; Irizarry *et al*., 2003a; Chu *et al*., 2004; James *et al*., 2004).

8. Software

Several software packages are available for the low-level data analysis of oligonucleotide expression arrays. MAS software (renamed to GCOS in 2003) is designed for analysis ranging from processing raw array images to calculating the gene expression indexes; dChip (Li and Wong, 2003) implements the invariant set and MBEI methods, as well as several high-level analysis functions such as hierarchical clustering and searching for functional and chromosomal enrichment in a list of genes; Bioconductor project (**www.bioconductor.org**) has developed many microarray data analysis packages (e.g., Affy package; Gautier *et al*., 2004) based on the R-statistical environment (Ihaka and Gentleman, 1996), and it allows users to normalize, calculate gene expression indexes using various methods, and do high-level analysis such as using graphs to represent pathways and linking genes to on-line databases by HTML page.

9. Prospects

There are researchers actively working on low-level microarray data analysis on the above-mentioned issues, such as improving background estimation and better utilization of probe sequence information. These were discussed in the two major workshops on low-level microarray analysis (GeneLogic workshop, 2001; Affymetrix Workshop, 2003). In the near future, generating large-scale benchmark datasets such as arrays hybridizing to multiple tissue types or hybridizing to samples with more genes spike-in at known concentrations will be of tremendous help to many research topics, including estimating the cross-hybridization background and developing model for index calculation and searching for more housekeeping genes. We also recommend not going too quickly in reducing the probe set size, since having more probes per probe set helps researchers to better understand the probe behaviors and develop more mature low-level analysis methods.

Short Specialist Review

CGH data analysis

Adam A. Margolin
Columbia University, New York, NY, USA

Adam A. Margolin, Joel Greshock and Barbara L. Weber
University of Pennsylvania, Philadelphia, PA, USA

1. Introduction

Genomic abnormalities, such as amplification or deletion of segments of DNA, are an important feature of cancer and other genetic disorders. Comparative genomic hybridization (CGH) has been widely employed since its introduction in 1992 to identify such chromosomal alterations (Kallioniemi *et al*., 1992). Using this technology, differentially labeled test DNA and reference DNA are hybridized simultaneously to normal chromosome spreads, the hybridization is detected with two different fluorochromes, and regions of gain or loss of DNA sequences are seen as changes in the intensity ratio of the two fluorochromes (Kallioniemi *et al*., 1992). With advances in array-based technologies, CGH has been implemented in a microarray format (Pinkel *et al*., 1998), enabling much higher resolution mapping of chromosomal alterations and providing more quantifiable results amenable to statistical and high-throughput analysis. Gene expression array platforms that have been adapted for array comparative genomic hybridization (aCGH) include two-channel arrays using genomic DNA from bacterial artificial chromosomes (BACs) (Pinkel *et al*., 1998) or cDNA clones (Greshock *et al*., 2004; Pollack *et al*., 1999), as well as single-channel oligonucleotide-based arrays (Bignell *et al*., 2004; Lucito *et al*., 2003). Although these aCGH assays share mechanical similarities with assays designed to measure gene expression, analysis and interpretation of aCGH data differs for several important reasons. First, expression arrays measure a nearly continuous spectrum of gene expression levels, whereas copy number arrays must quantify discrete changes in genomic copy number. Second, expression array probes can be treated as independent objects, each measuring the expression level of a single gene or mRNA species, whereas copy number array probes must be interpreted within the context of their genomic location and the surrounding probes, and can be used to define the overall pattern of chromosomal abnormalities throughout the genome. For copy number arrays that do not have full tiling

resolution genomic coverage, this data can be used to interpolate copy number changes for genomic regions not directly covered by a probe. Finally, normal diploid DNA provides a constant baseline value for comparison in CGH arrays. This review will discuss how to account for these differences to adapt well-studied techniques for analysis of gene expression array data to the analysis of aCGH data.

2. Probe value analysis

The test statistic output by most aCGH scanning and preprocessing software is typically the normalized spot fluorescence intensity ratio of a test-to-reference sample for two-channel arrays, where a ratio of 1.0 represents a diploid state in the test sample. For single-channel arrays, this statistic is typically the normalized spot fluorescence intensity. Ratio values are generally log-transformed, allowing amplification and deletion events to be treated symmetrically (although it should be noted that deletion events generally do not give zero signal due to low levels of "normal" contamination in patient tumor samples). To compensate for any potential dye-bias in two-channel arrays, replicate "dye swap" experiments can be performed in which the dyes used to label the test and reference sample are applied in both combinations. In this context, the geometric mean of the log values of each hybridization can be used to assign a single measure of representation to each probe in a dye swap experiment.

After obtaining measures for each probe in an experiment, this data must be transformed into interpretable statistics to most accurately determine the probability that a genomic region is amplified or deleted in a test sample. Transforming data into standard statistics also allows results from different assays and different experiments to be compared. The most widely employed and simplest approach to this problem is to use hard discretization of the data based on defined thresholds of the logarithm of the probe values to classify genomic regions as amplified, deleted, or normal, with possible additional thresholds representing homozygous deletions or multiple copy amplifications. For example, a genomic region covered by a probe may be considered deleted if the test-to-reference $\log_2$ ratio value is less then -0.25, and amplified if this value is greater than 0.25 (Veltman *et al*., 2003) (Figure 1). Optimally, a proper threshold can be determined by examining the distribution of ratios for regions of known aberrations in control assays.

A more sophisticated approach would account for systematic variation in probe values that can primarily occur from two sources (1) between-assay variation and (2) between-probe variation. First, differences in laboratory experimental conditions, variation in hybridization efficiency for different slides, the presence of contaminating normal tissue, and other sources of variation can lead to a distribution of measured representation across patients, even for regions that have identical copy numbers. One approach to address this variability is to adjust probe thresholds based on the overall distribution of probe values for a particular experiment (Snijders *et al*., 2003), although this can be problematic when analyzing highly aneuploid samples that may not produce accurate baseline distributions (Davidson *et al*., 2000). A mixture-model approach can also be used in which a mixture of three Gaussian distributions, corresponding to the normal, gained, and deleted

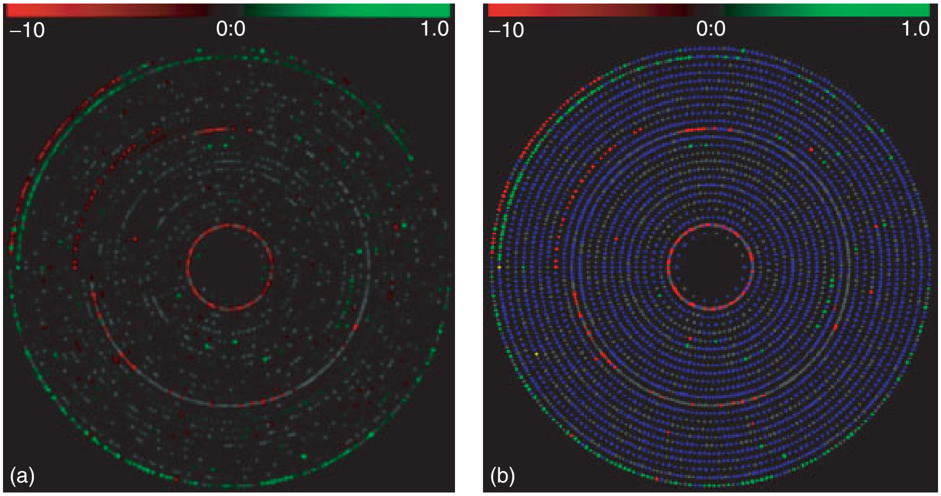

Figure 1 Circular display of the entire genome for a single aCGH experiment performed on a melanoma cell line. Chromosomes are displayed as concentric circles, with chromosome 1 presented as the outermost circle, followed by chromosome 2, and the Y chromosome presented as the innermost. Each dot represents an arrayed BAC clone probe, with the p-arm telomere of each chromosome beginning along the horizontal on the left of the display, and subsequent probes arranged clockwise by their linear order on the chromosome. (a) Probes are colored by a gradient based on the base 2 logarithm of the ratio of measured fluorescence intensities of the test sample relative to the unaltered reference. Log_2 ratios of 1 (representing likely amplifications) are displayed in bright green, and $\log_2$ ratios of -1 (representing likely deletions) are displayed in bright red, with gradients of color representing intermediate levels. Notice that a large portion of chromosome 1 appears to be amplified. The bright red circle toward the center represents the X chromosome, which appears to be "deleted" in this male-to-female hybridization. (b) Discrete determinations are made for the DNA copy number content represented by each probe using $\log_2$ threshold ratios of -0.25 and 0.25 for deletions and amplifications. Probes representing amplified and deleted DNA content are displayed as green and red dots, with probes representing normal (diploid) DNA content displayed as blue dots. Figures were produced using the CGHAnalyzer software package (Margolin *et al*., 2005)

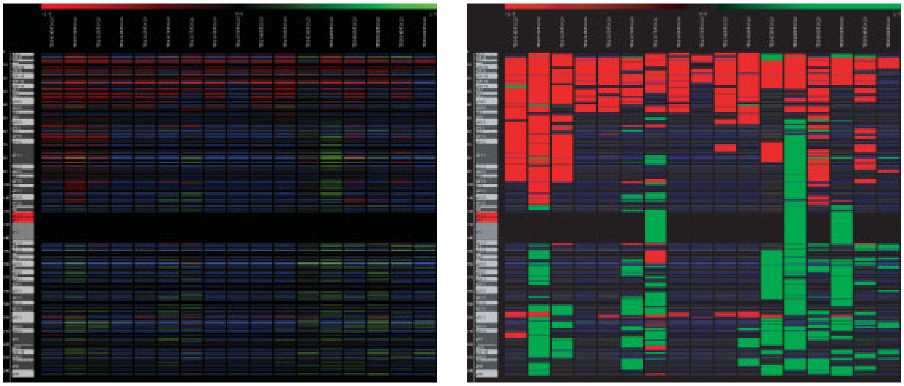
portions of the genome, is fitted to a histogram of the probe value ratios for each experiment. This approach was employed by Hackett *et al*. (2003) using a hybrid least-squares/maximum likelihood method. Another method, employed by Paris *et al*. (2004), determined sample-specific thresholds by using a discrete-time hidden Markov model (HMM) to segment probes on individual chromosomes into the states corresponding to underlying copy numbers.

Between-probe variation arises owing to variation in the probe sequence composition, including the presence of repetitive sequences, base composition, and differences in secondary structure, all of which can affect hybridization kinetics and which have been shown to alter the distribution of hybridization intensity values for different probes throughout experiments (Snijders *et al*., 2001). To address this problem, a reference data set of normal–normal hybridizations can be used to estimate the Gaussian distribution of signal intensity for each probe representing the distribution of values for cases where the probe covers a region of diploid DNA. The mean value of all replicate spots for a probe in a single experiment can be compared to the distribution for that probe calculated from the normal–normal dataset to assign a z-score representing the probability that the segment of DNA



covered by the probe is amplified or deleted in the test sample. Moore *et al*. (1997) employed a similar approach for analysis of traditional CGH experiments. However, this group compute a modified t-value, as described by Kendel and Stuart (1967), by comparing the distribution of values from replicate experiments to the distribution calculated from the normal–normal dataset.

Each of the methods described above attempts to address a different source of variation in probe value measurement. The most comprehensive method of transforming probe values to probabilities of chromosomal alterations should consider aspects of all of these models. More research is needed to formally define the limitations and capabilities of each method. Fortunately, analyzing X chromosome probe values for experiments that use DNA from a male as the test sample and DNA from a female as the reference sample provide a controlled setting for investigating each method's ability to detect heterozygous deletions.

3. Profile generation

In expression arrays, which are designed to measure the expression level of distinct mRNA species, the probes for each gene can be treated as independent objects. However, in using CGH arrays, which are designed to measure the DNA copy number profile across the entire genome, the spatial distribution of the probes across the genome and the correlations between signals from nearby probes provide important information for interpreting the results. Recently, tiling arrays that use a set of overlapping probes covering the genome have been used for comprehensive estimation of copy number variation (Ishkanian *et al*., 2004). However, most CGH arrays currently in use only directly measure copy numbers for a small percentage of the genome. These arrays are generally designed such that probes are evenly distributed across the genome, and copy number is estimated across the genome by interpolating the measurements for flanking regions. Defining a copy number profile across the entire genome, and not just at the location of the probes, allows comparison between arrays performed on different platforms. While arrays with nonoverlapping probes are the most commonly used, it should be noted that they can miss microamplifications and microdeletions whose boundaries lie completely between arrayed probes.

The most conservative method of interpolation for the region of DNA between arrayed probes is to assume that any copy number change measured by a probe extends on either side of the probe until the next probe of a different measured copy number (Figure 2). The authors tend to favor this conservative approach, although it overestimates the altered regions, because there is no way to accurately determine the break-point between two probes of differing copy number, so maximizing potential regions of alteration will not exclude potentially important genes. Another potential problem of this approach is identifying single, nonaberrant probes that break up otherwise large, contiguous regions of alteration (e.g., an entire chromosome arm). Although such noncontiguous regions of alteration certainly occur in real samples, a probe value that lies just within the alteration threshold is more likely to represent a true alteration given supporting evidence from nearby probes.

(a) (b)

Figure 2 Display of chromosome 1 for 17 CGH microarrays performed on neuroblastoma cells lines (Mosse *et al*., 2005). (a) Genomic coordinates in megabases and a chromosome ideogram are displayed on the left side of the graph, with arrayed BAC clone probes displayed as horizontal bars at positions corresponding to their genomic location. A discrete copy number determination is made for each probe using $\log_2$ threshold ratios of -0.25 and 0.25 for deletions and amplifications. Probes determined to represent regions of amplified or deleted DNA content are displayed in green and red respectively, with probes determined to represent normal diploid DNA displayed in blue. (b) DNA content for genomic regions not directly represented by arrayed probes is interpolated using the "flanking regions" approach to maximize potential alterations, producing an estimated whole-genome copy number profile. Genomic regions that are determined to be amplified or deleted in each sample are represented by green and red boxes in the graph

Therefore, thresholds should be relaxed for probes that lie within contiguous alteration regions. These thresholds could be adjusted by using a simple weighted average of neighboring probe values, or by employing a more sophisticated kernel-based function of neighboring probe values. For example, Snijders *et al*., (2003) have employed an unsupervised HMM to identify groups of probes with the same underlying copy number. A more recent approach (Myers *et al*., 2004) employs an EM-based edge placement algorithm to statistically optimize predicted alteration start and end locations, combined with a window significance test to determine the statistical significance of these predictions. We note that data smoothing methods that adjust every probe value on the basis of neighboring probe values reduce the ability to detect smaller, more localized regions of alteration, which have been shown to be of consequence in tumor samples (Reiter and Brodeur, 1996). Therefore, a smoothing method that only adjusts values for probes that lie between those that represent alterations may be more appropriate for aCGH analysis. More research is needed to evaluate the efficacy of various statistical methods that can be used to infer DNA copy number for genomic regions that are not directly measured.

4. Data visualization

We describe methods of visualizing aCGH data at three levels of granularity which, when used together, can provide a comprehensive representation of the chromosomal alteration profile across multiple experiments.

The most widely employed visualization method for viewing single experiments is a scatter plot of genomic location versus probe ratio values (Snijders *et al*., 2003). Probes representing normal diploid DNA should form a baseline of ratio values, and regions of chromosomal alterations can be identified visually as deviations from this baseline. For fine-resolution analysis of an experiment, this view must be displayed for a single chromosome, as displaying all chromosomes on a single graph often becomes cluttered for high-density arrays and this view does not accurately display boundaries between chromosomes. Plots of single chromosomes are often displayed next to a chromosomal ideogram, providing an easily interpretable view of chromosomal location (Chi *et al*., 2004).

A circular display can be used to represent data from the entire genome of a single sample in a compact form (Figure 1). This display consists of a number of concentric circles, each representing a chromosome, with chromosome 1 (the largest) presented as the outermost circle. Each circle is composed of a number of ordered spots, each representing an arrayed probe, and each colored on the basis of the probe intensity ratio in the given experiment. This view facilitates identification of large-scale abnormalities and the overall aneuploidy of a sample.

The typical view for visualization of multiple gene expression array experiments is a matrix or heap graph displaying each probe as a row and each sample as a column, with each cell colored by the probe value for the corresponding experiment. A modified version of this is typical for copy number visualization and can be applied to aCGH data to explicitly display probes by their chromosomal location. This display presents a chromosome ideogram on the left side of the screen with experiment arranged as columns, and a box for each probe colored by the probe's ratio value, beginning, and ending at the chromosomal location of the probe with reference to the chromosome ideogram (Figure 2). Alternatively, a display typically used for metaphase CGH, which displays vertical bars representing chromosomal gains on one side of a chromosome ideogram and vertical bars representing losses on the other, can be adapted for the display of aCGH data after interpolating a whole genome alteration profile.

5. Higher-order analyses

Many of the higher-order analysis techniques that are widely employed for expression array analysis have been used to analyze aCGH data. Techniques employing traditional t-tests have been used to distinguish tumor classes using expression array data (Olshen and Jain, 2002), and have recently been applied to aCGH data (Veltman *et al*., 2003). Several groups have employed statistical correlation measures and hierarchical clustering (Hackett *et al*., 2003; Jain *et al*., 2001; Wilhelm *et al*., 2002) on arrayed probes to attempt to identify cooperating loci, or to classify tumors on the basis of their DNA copy number profile. Although these studies demonstrate the potential of using aCGH data for tumor classification, overweighting large aberrations or genomic regions with higher densities of arrayed probes may produce misleading results. One method of addressing this problem, as employed by Veltman *et al*. (2003), is to define a priori a group of known oncogenes or tumor suppressor genes for a given tumor type and cluster based on

the DNA copy number status of only these genes. Of course, this method is limited in that it reduces the size of the dataset and ignores potential novel aberrations that may be important for understanding the disease. Fritz *et al*. (2002) demonstrated that machine-learning approaches could also be applied effectively to aCGH data by showing that support vector machines (SVM) were able to reliably distinguish between pleomorphic liposarcomas and dedifferentiated liposarcomas, and that an SVM applied to aCGH data outperformed an SVM applied to expression array data in class differentiation.

6. Conclusion

Determination of chromosomal alterations associated with cancer and other genetic diseases is an important tool for understanding their pathogenesis. aCGH is an emerging technology aimed at answering this question at an unprecedented level of resolution. As aCGH shares many similarities to gene expression arrays, many aCGH analysis methods can be adapted from well-studied and established gene expression array analysis methods. However, analysis of aCGH data presents novel challenges, and as this technology becomes a widely employed tool in many laboratories, additional methods to analyze this data must be developed and improved. Most important will be to develop sound statistical methods for determining the likelihood that aCGH measurements represent chromosomal alterations, for using aCGH data to infer whole-genome copy number profiles, and for adapting higher-order analysis techniques to aCGH data for disease classification and identification of cooperating/associated loci.

Short Specialist Review

A comparison of existing tools for ontological analysis of gene expression data

Purvesh Khatri and Sorin Draghici
Wayne State University, Detroit, MI, USA

1. Introduction

Microarrays (*see* Article 90, **Microarrays: an overview**, Volume 4, Article 92, **Using oligonucleotide arrays**, Volume 4, and Article 100, **Protein microarrays as an emerging tool for proteomics**, Volume 4) are at the center of a revolution in biotechnology, allowing researchers to simultaneously monitor the expression of tens of thousands of genes. Independent of the platform and the analysis methods used, the result of a microarray experiment is, in most cases, a list of genes found to be differentially expressed between two or more conditions under study. The more recently proposed protein microarrays are also producing a list of differentially regulated proteins that can be mapped to their respective genes. The common challenge faced by the researchers using any of these techniques is to translate such lists of differentially regulated genes into a better understanding of the underlying biological phenomena. A first step in this direction can be the translation of the list of differentially expressed genes into a functional profile able to offer insight into the cellular mechanisms relevant in the given condition. As recently as 2002, an automatic ontological analysis approach has been proposed to help with this task (Khatri *et al*., 2002). Currently, this approach is the de facto standard for the secondary analysis of high-throughput experiments, and a large number of tools have been developed for this purpose.

This paper presents a review of this approach and a comparison of 14 current tools in this area. A detailed analysis of the capabilities of these tools, of the statistical models deployed as well as of their back-end annotation databases (if applicable), is included here in order to help researchers choose the most appropriate tool for a given type of analysis.

2. Ontological analysis – problem description

2.1. Gene ontology

Manually querying available Web-based annotation databases in order to find the functions associated with various genes is inherently slow and error prone.

An alternative approach to manual database queries and literature searches is an automatic analysis performed by a computer. However, an automatic high-level analysis cannot be performed if the functional annotations are stored as free text because of issues such as the imprecision of the terms, synonymy (different terms used for the same concept), and polysemy (same term used for different concepts). A solution to this vocabulary problem was provided by the Gene Ontology (GO) (Ashburner, 1998; Ashburner *et al*., 2000; Ashburner *et al*., 2001). The goal of GO is to provide an organism-independent, controlled vocabulary as knowledge of gene and protein roles in cells is being accumulated (Ashburner *et al*., 2000). GO is organized in three principal categories: molecular functions, biological processes, and cellular components. A gene or a gene product can have one or more molecular functions, can participate in one or more biological processes, and might be associated with one or more cellular components. Currently, all existing tools for ontological analysis use GO.

2.2. *Building functional profiles*

The translation from a list of differentially expressed genes to a functional profile able to offer insight into the cellular mechanisms is a very tedious task if performed manually. Typically, one would take each regulated gene, search various public databases and compile a list with, for instance, the biological processes that the gene is involved in. This task must be performed repeatedly for each gene in order to construct a master list of all biological processes in which at least one gene is involved. Further processing of this list provides a set of those biological processes that are common between several of the regulated genes. It is expected that those biological processes that occur more frequently in this set would be more relevant to the studied condition. The same type of analysis is necessary for molecular functions and cellular components.

The following example will illustrate this ontological analysis approach (Drăghici *et al*., 2003b). Let us consider an array containing 1000 genes used to investigate the effect of a substance X. Using classical statistical and data analysis methods, we decide that 100 of these genes are differentially regulated by substance X. Let us assume that the 100 differentially regulated genes are found to be involved in the following biological processes: 80 of the 100 genes are involved in *positive control of cell proliferation*, 40 in *oncogenesis*, 30 in *mitosis*, and 20 in *glucose transport*. This type of automatic processing is tremendously useful since they save the researcher the inordinate amount of effort required to process each of the 100 genes, compile lists with all biological processes, and then cross-compare those biological processes to determine how many genes are in each process (Khatri *et al*., 2002). In comparison, a manual extraction of this information would literally take several weeks and would be less reliable and less rigorous.

2.3. *Significance analysis*

The large number of genes involved in cell proliferation, oncogenesis, and mitosis in the functional profile above, might suggest substance X is involved in cancer

Table 1 Statistical significance. The number of genes involved in a given biological process can be misleading on its own. In this example, positive control of cell proliferation may appear to be the most important biological process affected since 80 of the 100 differentially regulated genes are involved in it. However, this process loses its significance when placed in the context that 800 of the 1000 genes on the chip are involved in it

Biological process	Genes found	Genes expected	Significance
Positive control of cell proliferation	80	80	Not significant
Oncogenesis	40	40	Not significant
Mitosis	30	10	Significant
Glucose transport	20	5	Highly significant

mechanisms. However, a reasonable question is: what would happen if all genes on the array were involved in cell proliferation? Would the presence of cell proliferation at the top of the list be significant? Clearly, the answer is no. If most or all genes on the array are involved in a certain process, the fact that particular process appears at the top is not significant. In order to correct this, any software implementing this approach should be able to consider the microarray used in the experiment, calculate the expected number of occurrences of each category, and compare them with the observed numbers.

Table 1 shows this comparison for the example above. Now, the interpretation of the functional profile appears to be completely different. There are indeed 80 *cell proliferation* genes but in spite of this being the largest number, we actually expected 80 such genes, and therefore this event is not significant. The same holds true for *oncogenesis*. *Mitosis* starts to be interesting because we expected 10 genes and we observed 30, which is 3 times more than expected. However, the most interesting process is the *glucose transport*. We expected only 5 genes and we observed 20, that is, 4 times more than expected. The emerging picture changes radically: instead of generating the hypothesis that substance X is a potential carcinogen, we may consider the hypothesis that X is correlated with diabetes.

The problem is that an event such as observing 30 genes when we expect 10 can still occur just by chance. A simple enrichment analysis comparing, for instance, the proportion of genes in a certain category between the entire set of genes and the selected set of genes will not be sufficient since almost any proportion can occur with a nonzero probability. It is the magnitude of this probability that will determine whether a specific category is significant or not. Hence, it is important that any ontological analysis software calculate the probability of a certain proportion occurring just by chance.

3. Existing tools for ontological analysis

The ontological analysis approach described above was first proposed in 2001 by Onto-Express (Khatri *et al*., 2002). The statistical approach used to calculate the significance of various categories followed one year later (Drăghici *et al*., 2003b). From 2003 to 2005, 13 other tools have been proposed for this type of analysis and more tools continue to appear everyday. By and large, all these tools use the same approach. The tools discussed here are FatiGO (Al-Shahrour

et al., 2004), GOstat (Beissbarth and Speed, 2004), eGOn Explore Gene Ontology (eGOn, 2005), DAVID (Dennis *et al*., 2003), GeneMerge (Castillo-Davis and Hartl, 2002), FuncAssociate (Berriz *et al*., 2003), CLENCH (Shah and Fedoroff, 2004), GOToolBox (Martin *et al*., 2004b), GOSurfer (Zhong *et al*., 2004), EASE (Hosack *et al*., 2003), OntologyTraverser (Young *et al*., 2004), GoMiner (Zeeberg *et al*., 2003), and GOTree Machine (Zhang *et al*., 2004). Figure 1 provides a time line of the development of these tools. The following represents our best attempt to compare these tools on the basis of the review of the published manuscripts, user manuals, and our experience with each tool. In addition to functional profiling, GO has also been used for many other purposes such as predicting annotations of unknown sequences (Khan *et al*., 2003; Martin *et al*., 2004a) or measuring the semantic functional similarity between genes (**http://194.117.20.201/tools/ssm/**, 2003). Such applications are outside the scope of this paper. In the following, we first describe each tool very briefly and then compare their capabilities and features.

Onto-Express (OE) was the first tool to propose the automated functional profiling through the integration of dbEST (Boguski *et al*., 1993a,b), UniGene (Schuler, 1997), and LocusLink (Pruitt *et al*., 2000) databases in the Onto-Tools database. The current version of OE supports KEGG, Entrez Gene, PubMed, RefSeq, GenBank, and Gene Ontology databases. OE's back-end database is currently being expanded to integrate GenPept, Protein Information Resource (PIR), Protein Data Bank (PDB), Swiss-Prot, TrEMBL, Online Mendelian Inheritance in Mammals (OMIM), HomoloGene, and Eukaryotic Promoter Database (EPD) databases.

At present, OE can process lists of genes specified as GenBank accession IDs, UniGene cluster IDs, LocusLink IDs, Affymetrix probe IDs, gene symbols, or WormBase accession IDs (Figure 2). OE's output is organized in various views that include: (1) a flat view, which is a bar-graph view that only considers the annotations at the most specific level, (2) a tree view, which represents the results in a custom cut through the GO hierarchy, and (3) a synchronized view, which is

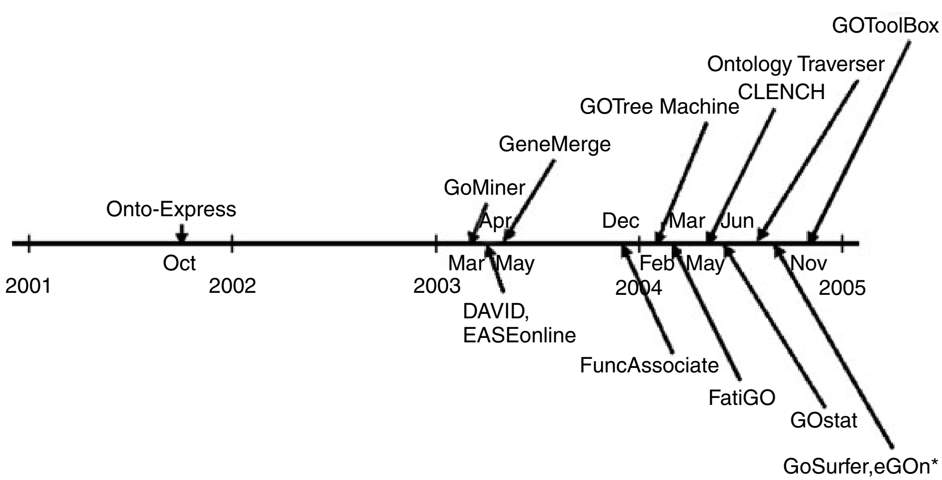

Figure 1 Evolution history of GO-based functional analysis software. The tool marked with a star (eGOn) has not been published in a peer-reviewed journal yet

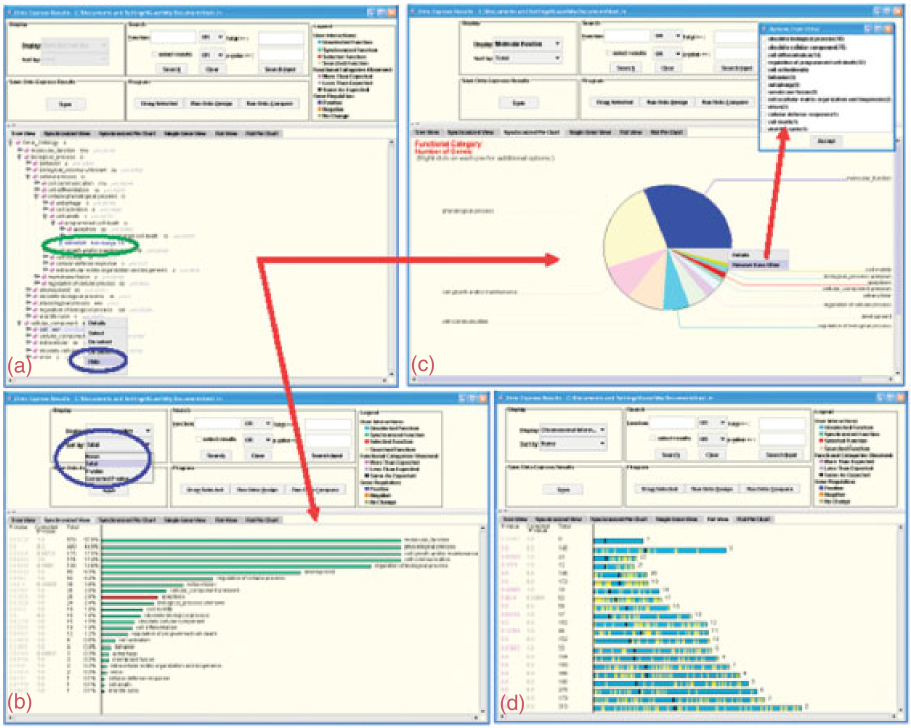

Figure 2 Onto-Express output interface: tree view (a), synchronized bar-chart view (b), synchronized pie-chart view (c), and chromosome view (d). The user can select different levels of abstraction for different branches of the GO hierarchy in the tree view by expanding or collapsing the desired nodes (a). Switching to the synchronized bar-chart view performs the analysis on the GO terms selected in the tree view (b). The tree view also displays the fold change value for an input gene as provided by the user (highlighted in a). In the synchronized view, results can be sorted by name, by total number of genes for each term, by p-value or by corrected p-value (highlighted in b). Categories in the pie chart can be added or removed by the user

a custom bar-graph synchronized with the tree view. The combination of the tree and synchronized views allows the user to select a custom level of abstraction for each branch of the Gene Ontology. This allows the user to ask specific questions about the phenomenon studied. For instance, one could ask whether the apoptotic pathway as a whole is affected without making the distinction between various subprocesses such as positive or negative regulation of apoptosis, induction of apoptosis by various causes (e.g., extracellular signals, intracellular signals, hormones), and so on. In such cases, the user can use OE's tree view to collapse the categories that are unnecessarily specific into more abstract categories. For instance, the approximately 40 subcategories of apoptosis can be collapsed into a single *apoptosis* node. Subsequently, the analysis will be done at this level of abstraction, directly providing the answer to the desired question. A more detailed discussion of this issue and its consequences are included in Section (4).

The Onto-Tools database currently includes 172 arrays from 8 manufacturers that can be selected as the reference. Any other array can be uploaded by the user as a custom reference array. A distinguishing feature of OE is the ability

to sort the entire GO tree by the total number of genes, *p*-values or terms. Another unique feature is a chromosomal location profile that shows the location of the various differentially regulated genes on various chromosomes (however, this feature is currently available only for human genes). Onto-Express also features an application programming interface (API) that allows any other bioinformatic tool to place queries and display the results of the analysis. This capability is currently used by two commercial companies (Insightful and SAS), which integrated OE with their respective software packaged for microarray data analysis: S + ArrayAnalyzer and SAS' Microarray Solution.

GoMiner relies on the Gene Ontology database and can only process gene symbols as input. The same group provides a separate tool, MatchMiner, which converts other types of IDs into gene IDs that are appropriate for use with the GoMiner. This does allow the user to perform the analysis using other types of IDs but adds a separate step to the analysis pipeline since the user has to manually take the results from MatchMiner and submit them to GoMiner.

By default, GoMiner's analysis is not organism specific (Figure 3). This means that if a gene is annotated with function A in one organism and function B in another organism, GoMiner will treat it as if it were annotated with A *and* B, independent of the organism that is actually studied. The user has to choose the

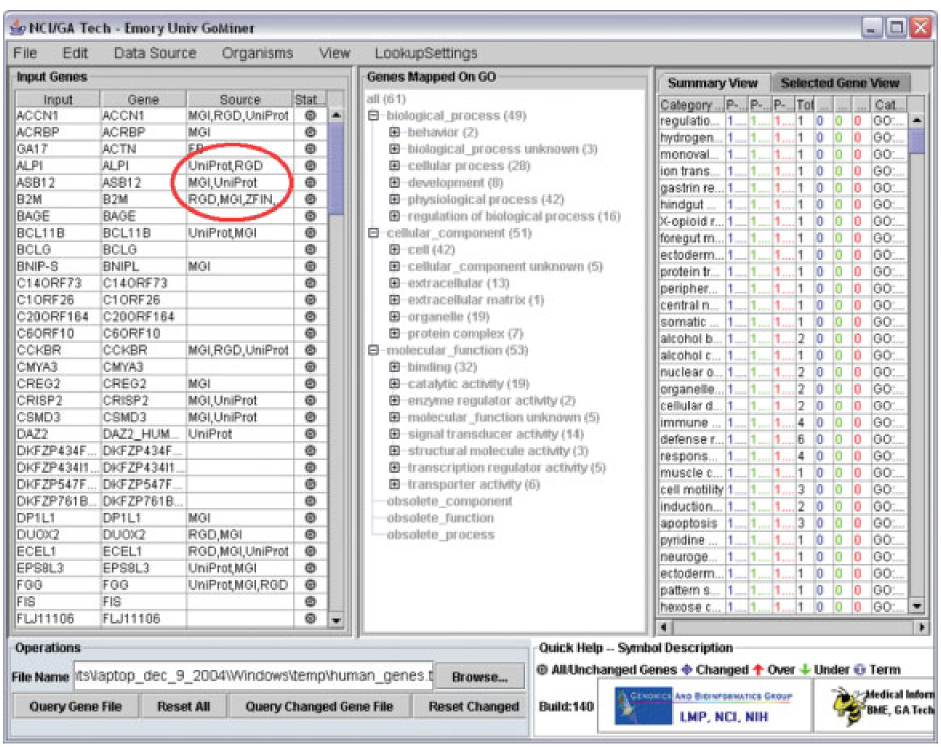

Figure 3 GoMiner output. By default, GoMiner results lack organism specificity. In response to a query with human genes, GoMiner can return annotations from either one of MGD (mouse), RGD (rat), ZFIN (*D. rerio*), and FlyBase (*D. melanogaster*)

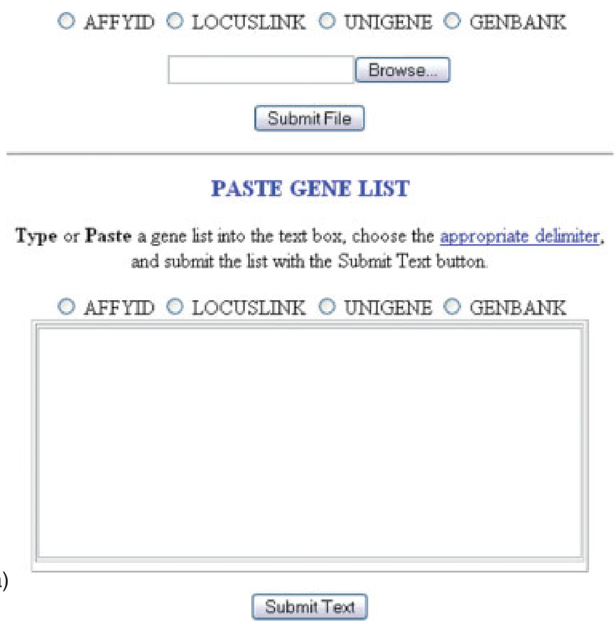
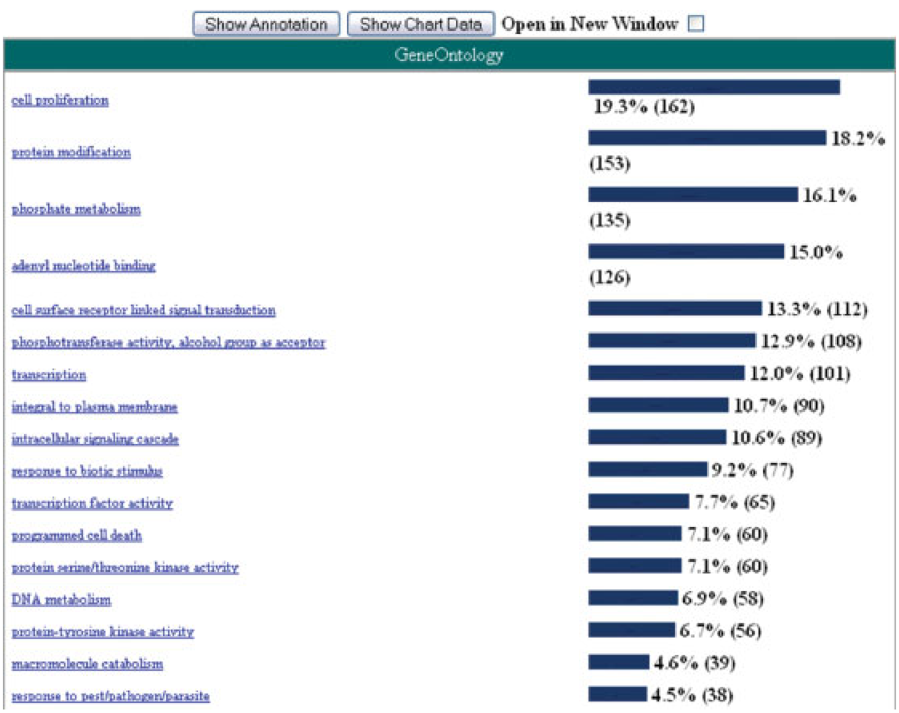
desired organism and/or the appropriate data source from the menu to restrict the results to a specific organism. GoMiner is able to represent the results graphically as a directed acyclic graph (DAG). This is achieved using an Adobe scalable vector graphics (SVG) web browser plug-in, which is only compatible with MS Windows. In consequence, GoMiner is platform dependent (Windows only) although it is written in Java and could, in principle, be used on other platforms, as well.



DAVID and EASEonline. DAVID (Database for Annotation, Visualization and Integrated Discovery) provides an HTML-based interface that allows the user to query using a set of genes. The results are presented as a bar chart indicating the percentage of the input genes for each GO term. The results are very simple, do not consider the GO hierarchical structure, and do not calculate any p-value to characterize the statistical significance of the observed results. On the plus side, DAVID does allow the user to specify a depth of analysis, which can be used to perform a horizontal cut through the GO hierarchy.

EASE (Expression Analysis Systematic Explorer) is a companion to DAVID. EASE allows the user to submit Affymetrix IDs, UniGene cluster ID, LocusLink ID, or GenBank accession IDs and calculates the p-values of various categories using Fisher's exact test. As shown in Figure 4, EASE does not consider or show the ontological categories in the context of the hierarchical structure of GO. EASE currently supports 27 Affymetrix arrays as possible reference arrays.



GeneMerge only accepts organism-specific gene IDs used by the various organism-specific annotation groups to deposit functional annotations in the GO Consortium database. Although in principle, it supports more types of IDs as input, its usefulness is somewhat limited since it does not support commonly used IDs such as GenBank accession numbers, RefSeq mRNA, protein IDs, and so on. In order to address this, GeneMerge's authors have recently provided a gene name converter that translates a larger set of IDs into the required format accepted by GeneMerge. As a limitation, GeneMerge only allows to query one of the three principal GO categories at a time. Outstanding features for GeneMerge include the ability to query a few organism-specific features such as KEGG metabolic and signaling pathways for yeast and fruit fly, and deletion viability data for yeast, and so on (Figure 5).

FuncAssociate uses Fisher's exact test to calculate the p-values and a Monte-Carlo simulation to correct for multiple hypothesis testing (Figure 6). FuncAssociate allows the user to submit a rank-ordered list of genes as input, such as a list of genes ranked by fold changes. Given this, FuncAssociate ranks the GO terms in the result according to which initial segment of the input list gives the most significant degree of over- or underrepresentation, where the initial segment for each gene g in the original ordered set Q, is the subset of Q consisting of g plus all the genes that precede g in the given order (Berriz *et al*., 2003).

GOTree Machine (GOTM) has the ability to visualize the results both as a hierarchical tree as well as a bar chart (Figure 7). However, GOTM requires the user to select a specific depth in the GO hierarchy, before displaying a bar chart. GOTM supports 37 Affymetrix arrays as reference arrays. A key aspect of GOTM is the performance. The output interface of GOTM is based on HTML, which means that every user interaction, such as a request to expand a GO term or a request to retrieve a list of input gene IDs, is an HTTP request over the Internet. This is reflected in a

(a)

(b)

Figure 4 EASE input (a) and output (b) interface. EASE supports GenBank accession IDs, Affymetrix probe IDs, UniGene cluster IDs, and LocusLink IDs as input. The user can either submit a file containing the input IDs or paste the input IDs in the text area (a). EASE does not consider the hierarchical structure of the GO in the analysis (b)

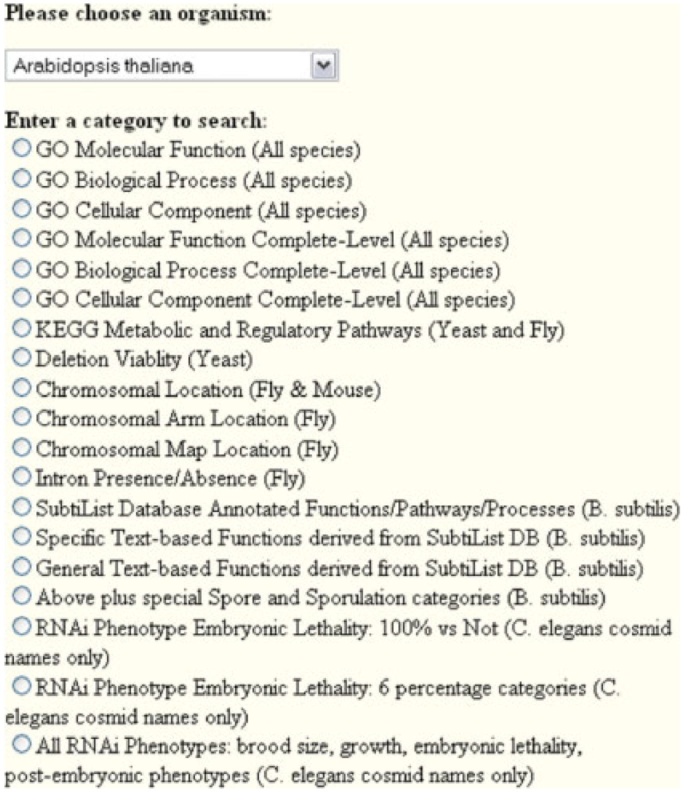


Figure 5 GeneMerge input interface. In addition to functional profiling, GeneMerge also allows to query for KEGG pathways and chromosomal location for yeast and fly, RNAi phenotypes for *C. elegans*, and functions, processes and pathways for *B. subtilis*

slower performance compared to GoMiner or to Onto-Express, which only query their respective back-end database once, after which all processing is done locally.

FatiGO is also a Web-based tool. FatiGO performs the analysis on only one of the three principal GO categories per request and requires the user to select the depth in the GO at the beginning of the analysis (Figure 8). However, the analysis can only be performed up to the 6th level in the GO hierarchy. FatiGO displays the results both as a bar chart as well as a completely expanded GO tree in a single HTML page. If the input only contains a relatively small number of genes (e.g., fewer than 50) and the number of GO terms is limited, this display is informative and convenient since little or no page scrolling is required. However, if the input list contains a few hundreds of genes, which usually yields a functional profile with a few thousand GO terms, the single page display becomes overwhelming.

CLENCH is a command-line, stand-alone tool specifically designed for *Arabidopsis thaliana*. At the moment, CLENCH uses TAIR as a unique source of annotations. In consequence, *A. thaliana* annotations originated at TIGR may not be considered in the analysis. CLENCH retrieves the annotations for *A. thaliana* at runtime from the TAIR website. Similar to FatiGO, CLENCH also outputs the

Figure 6 FuncAssociate output interface. FuncAssociate allows the user to submit a rank-ordered list of genes as input. The GO terms in the results are then ordered in the increasing order of the p-values. The ranks of the GO terms are displayed in the first column and their p-values are displayed in the fifth column

results as a single HTML file. Unlike FatiGO, it does not show or consider the hierarchical structure of GO. The local installation of CLENCH requires a previous installation of Perl as well as specific Perl modules. Hence, the initial deployment of CLENCH as well as its command-line interface may be a bit uncomfortable for a typical life scientist.

GOstat is another Web-based tool (Figure 9). It supports *Homo sapiens*, *Mus musculus*, *Rattus norvegicus*, *Arabidopsis thaliana*, *Danio rerio*, *Caenorhabditis elegans*, and *Drosophila melanogaster*. Similar to EASE and FatiGO, GOstat requires the user to select the level of abstraction in the GO hierarchy. GOstat supports GenBank accession number, UniGene cluster IDs, gene symbols and various organism-specific IDs. GOstat represents the results in an HTML or tab-delimited text file, which does not consider the GO hierarchy. GOstat offers false discovery rate (FDR) or Holm's correction for multiple hypothesis testing.

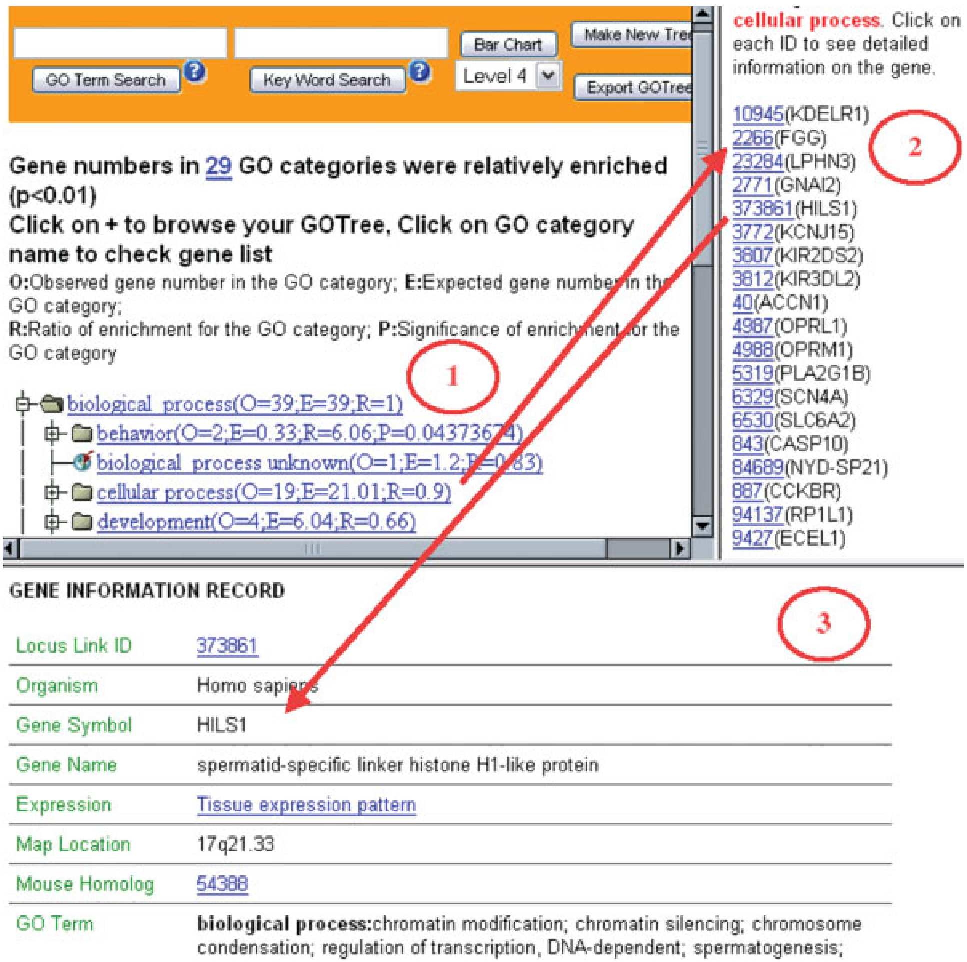

Figure 7 GOTree Machine (GOTM) output. GOTM results are organized in three frames as numbered in the figure. The first frame displays the results in the GO hierarchy. Clicking a GO category in the first frame displays the input genes annotated with the GO category in the second frame. Clicking on a gene in the second frame presents more details about the gene such as the gene name and symbol, LocusLink ID, location on a chromosome, and so on, in the third frame

GOToolBox is also a Web-based tool and supports *Arabidopsis thaliana*, *Drosophila melanogaster*, *Mus musculus*, *Homo sapiens*, *Caenorhabditis elegans*, and *Saccharomyces cerevisiae* (Figure 10). GoToolBox only supports the organism-specific IDs used in the GO database. GOToolBox either requires the user to select a specific depth in the GO hierarchy or considers the lowest level in the GO hierarchy.

GoSurfer is available as a stand-alone application and supports Affymetrix probe IDs, LocusLink IDs, and UniGene cluster IDs as input. It requires the user to download a specifically formatted GO structure file and at least one gene information file that is also specifically formatted. It displays the results as a DAG on which zoom operations are possible. However, none of the nodes in the DAG

(b)

Figure 8 FatiGO input (a) and output (b) interface. FatiGO only allows to query one of the three principal GO categories at a time. As seen in the highlighted area, FatiGO either uses the entire genome or only the genes annotated with GO terms as the reference. FatiGO presents the results as bar charts as well as a completely expanded GO tree in a single HTML page (b)

are labeled, which makes it very difficult for the user to interpret the results or look for a specific GO term.

OntologyTraverser is described (This is the only tool that we could not use ourselves. In spite of numerous attempts over several weeks, we always encountered the following error: “Error unmarshaling return header; nested exception is: java.io.EOFException”.) as a Web-based tool as well as an R package. Its Web-based version allows the user to query one GO category at a time and calculates the *p*-values using a hypergeometric distribution. However, the model seems to be applied rather differently: instead of considering the number of genes for a given GO term, this tool seems to use the number of genes annotated with the terms at the same level in GO (Young *et al*., 2004). If this description is accurate, this usage of the hypergeometric model may be difficult to justify from a biological point of view.

eGOn. Similar to EASE, GeneMerge, FatiGO, and Ontology Traverser, eGOn only allows the user to query one of the three main GO categories at a time (Figure 11). The analysis performed by eGOn is centered around UniGene clusters.

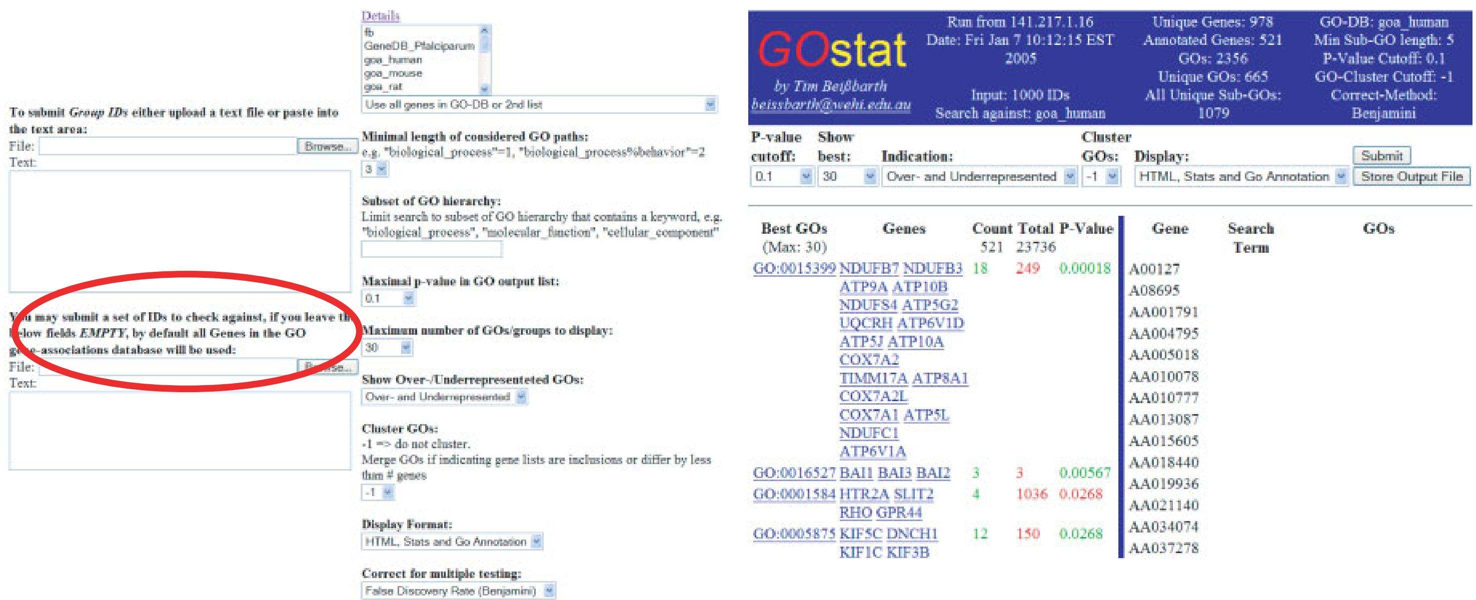

Figure 9 GOstat input and output interface. GOstat requires that the user must upload a reference gene list. Otherwise, it uses all genes in the GO database as the reference. The gene names in the GOstat output are hyperlinked to GeneCards database

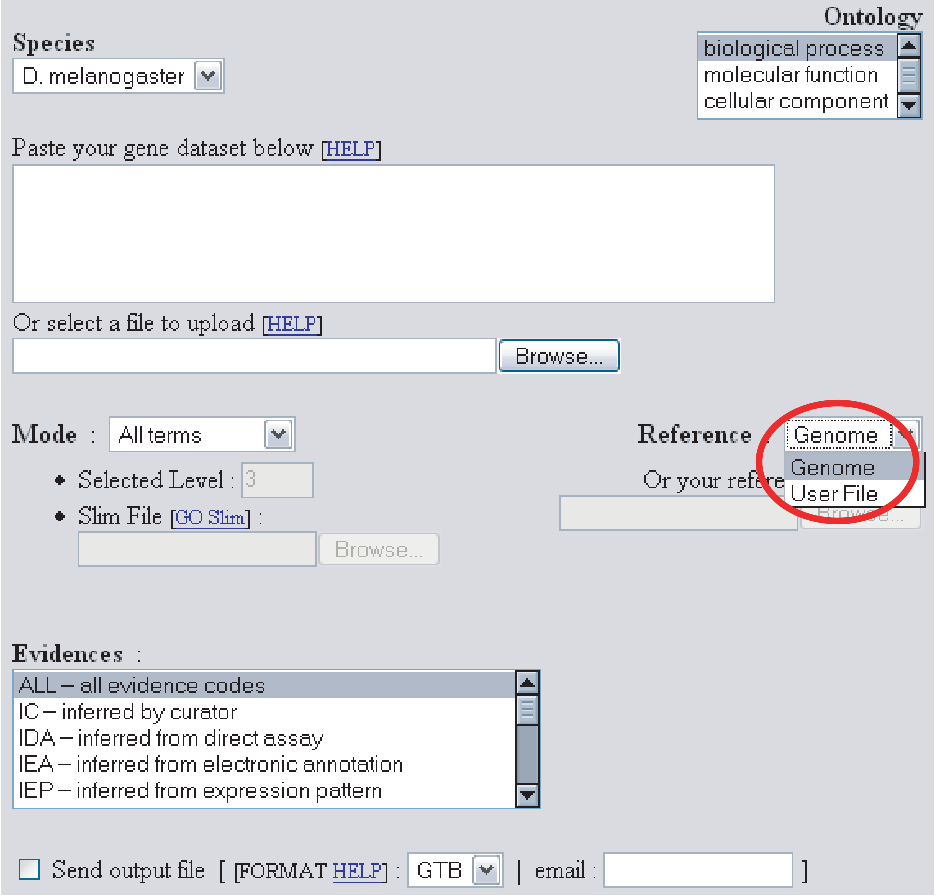

Figure 10 GOToolBox input interface. GOToolBox allows to filter the annotations by evidence codes. If the user does not specify the reference list of genes, GOToolBox uses the genome as the reference

The fundamental implicit assumption here is that each UniGene cluster corresponds to distinct genes. However, this assumption may not always be accurate. UniGene has been created by comparing expressed sequence tags (ESTs) in the dbEST database (Schuler, 1997). However, owing to the alternative splicing of the mRNA, it is entirely possible that ESTs from the same gene cluster in different groups, which will result in several UniGene clusters being associated with the same gene. As an example, the SET8 gene (*SET8: PR/SET domain containing protein 8*, LocusLink ID: 387893) is associated to UniGene clusters Hs.443735 and Hs.536369. If a study includes any such gene, treating each UniGene cluster as a distinct gene, as eGOn does, may not always be appropriate. In such circumstances, the results can be skewed toward those GO terms that are associated to genes from which more than one UniGene clusters are derived. This may become particularly important if further research will confirm the current estimates that up to 90% of the human genes may have alternative splice variants.

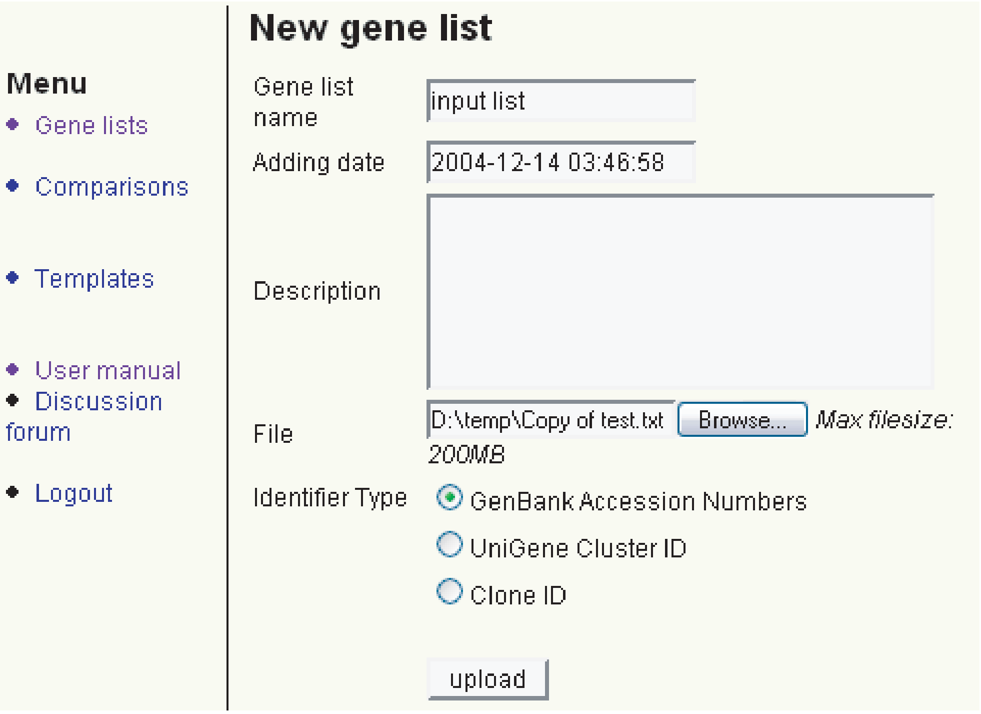

Figure 11 eGOn input interface. eGOn requires that each gene list and each data analysis is given a unique name. The gene lists and analysis are stored on the server for 30 days

4. Comparison of existing functional profiling tools

The criteria used to compare the ontological analysis tools are described in details in the following.

4.1. *The statistical model*

The ontological analysis can be performed with a number of statistical models including hypergeometric (Cho *et al*., 2001), binomial, χ^2 (chi-square) (Fisher and van Belle, 1993), and Fisher's exact test (Man *et al*., 2000). The use and applicability of these tests have been discussed in the literature (Drăghici, 2003; Drăghici *et al*., 2003a,b). More recent tools continue to use one or several of these models (Beissbarth and Speed, 2004; Berriz *et al*., 2003; Martin *et al*., 2004b; Young *et al*., 2004; Zeeberg *et al*., 2003; Zhang *et al*., 2004). GoMiner, EASEonline, GeneMerge, FuncAssociate, GOTM, GOToolBox, GOSurfer, OntologyTraverser, and eGOn only support one statistical test. GOstat allows the user to choose between two tests (χ^2, and Fisher's exact test), CLENCH allows a choice between three tests (χ^2, hypergeometric, and binomial), while Onto-Express implements all four tests (χ^2, hypergeometric, binomial, and Fisher's exact test).

4.2. The set of reference genes

An important consideration when identifying statistically significant GO terms is the choice of the reference list of genes against which the p-values for each GO term in the results are calculated. Several tools such as GOToolBox, GOstat, GoMiner, FatiGO, and GOTM (GOTM also allows the users to upload their own list of genes or use one of 37 Affymetrix arrays as the set of reference genes.) use the total set of genes in a genome as the reference (Beissbarth and Speed, 2004; Martin *et al*., 2004b; Zeeberg *et al*., 2003; Zhang *et al*., 2004) or the set of genes with GO annotations (Al-Shahrour *et al*., 2004). Either of these may be an inappropriate choice when the input list of genes to these tools is a list of differentially expressed genes obtained from a microarray experiment, since the genes that are not present on a microarray do not ever have a chance of being selected as differentially regulated. The fundamental idea here is to assign significance to various functional categories by comparing the observed number of genes in a specific category with the number of genes that might appear in the same category if a selection performed *from the same pool* were completely random. If the whole genome is considered as the reference, the pool considered when calculating the random choice includes all genes in the genome. At the same time, the pool available when actually selecting differentially regulated genes includes only the genes represented on the array used, since a gene that is not on the array can never be found to be differentially regulated. This represents a flagrant contradiction of the assumptions of the statistical models used.

4.3. Correction for multiple experiments

Another crucial factor in the assessment of a functional category is the correction for multiple experiments (see, for instance, Chapter 9 in Drăghici, 2003). This type of correction must be performed in all situations in which the functional category is *not* selected a priori and many such categories are considered at the same time. The importance of this step cannot be overstated and has been well recognized in the literature (Al-Shahrour *et al*., 2004; Beissbarth and Speed, 2004; Berriz *et al*., 2003; Castillo-Davis and Hartl, 2002; Drăghici, 2003; Shah and Fedoroff, 2004; Zeeberg *et al*., 2003). In spite of this, several of the tools reviewed here do not perform such a correction: GoMiner, DAVID, GOTM, CLENCH, and eGOn. GoMiner provides a "relative enrichment" statistic calculated as $R_e = \frac{n_f/n}{N_f/N}$, where n and N are the numbers of genes in the selected and reference sets, respectively, and n_f and N_f are the number of genes in the functional category of interest in the selected and reference sets, respectively (Zeeberg *et al*., 2003). However, this relative enrichment cannot be used in any way as a correction for multiple experiments (Note that this statistic does not take into consideration the number of experiments performed in parallel.) but rather as another indication of the significance of the given category, somewhat redundant to, but less informative than the p-value. This statistic can be misleading because the user will be tempted to assign biological meaning to all those categories that are enriched. In reality, any particular relative enrichment value can actually appear with a nonzero probability just by chance. It

is the magnitude of the probability that should be used to decide whether a category is significant or not, rather than the relative enrichment.

All remaining tools deal with the problem of multiple comparisons in some way. EASEonline, GeneMerge, and GOToolBox support the Bonferroni correction. Bonferroni and Šidák are perfectly suitable in many situations, in particular, when not very many functional categories are involved (e.g., fewer than 50). However, these corrections are known to be overly conservative if more categories are involved (Drăghici, 2003). A family of methods that allow less conservative adjustments of the p-values is the Holm step-down group of methods (Hochberg and Tamhane, 1987; Holland and Copenhaver, 1987; Holm, 1979; Shaffer, 1986).

Bonferroni, Šidák, and Holm's step-down adjustment are statistical procedures that assume that the variables are independent, which is known to be false for this type of analysis (The very hierarchy of the GO on which this type of analysis relies shows that many biological categories are very closely related, sometimes as children of the same node on the next level up.). For this type of analysis, when it is known that dependencies exist, methods such as false discovery rate (FDR) are more appropriate (Benjamini and Hochberg, 1995; Benjamini and Yekutieli, 2001; Drăghici, 2003). If the dependencies are very strong (e.g., several subprocesses of the same larger process), a bootstrap or Monte-Carlo simulation approach may be better able to capture these dependencies, but only if enough categories are present to make the simulation meaningful.

The tools offering more than one correction method effectively allow the researcher to adapt the analysis to the number of categories and degree of known dependencies between them. The one tool standing out regarding this criterion is FuncAssociate, which uses a more original Monte-Carlo simulation. FatiGO and GOStat implement Holm's and FDR corrections. Onto-Express offers Bonferroni, Šidák, Holm's, and FDR.

4.4. The scope of the analysis

An important factor in assessing the usefulness of a tool is its ability to provide a complete picture of the phenomenon studied. In terms of functional profiling using GO, a complete analysis should include all three primary GO categories: molecular function, biological process and cellular component as well as other information if available. Among the tools reviewed, eGOn, FatiGO, GeneMerge, and OntologyTraverser only analyze one category at a time. The other tools allow the user to analyze all three categories simultaneously. Extra features are present in GeneMerge and Onto-Express. GeneMerge shows KEGG metabolic and signaling pathways for yeast and fruit fly, and deletion viability data for yeast. Onto-Express also shows KEGG metabolic and signaling pathway data, as well as a chromosome location of differentially regulated genes (linking to NCBI's Mapviewer for further analysis).

4.5. Visualization capabilities

The GO is organized as a directed acyclic graph (DAG), which is a hierarchical structure similar to a tree where, unlike a tree, a node can have several parents.

However, the DAG structure may not be the best choice for navigational purposes since it tends to clutter the display (Zeeberg *et al*., 2003). An alternative way to visualize the DAG structure of the GO is to represent and visualize it as a tree structure in which a node with several parents is represented in the tree multiple times, once under each parent. Any tool using GO for functional profiling of a list of genes should be able to graphically represent the hierarchical relationships between various functional categories, which allows the user to better understand the phenomenon studied. Furthermore, the functional analysis can be continued and refined by exploring certain interesting subgraphs of the GO hierarchy.

Among the tools reviewed, CLENCH, DAVID, EASEonline, FuncAssociate, GOstat, GOToolBox, and Ontology Traverser do not show the results in the context of the hierarchical structure of GO. Onto-Express, eGOn, FatiGO, GoMiner, and GOTM represent the results in their GO context. Onto-Express also allows sorting and searching operations in the hierarchy, appropriately expanding and/or collapsing nodes if necessary.

4.6. Custom level of abstraction

In the hierarchical structure of the GO, the genes are annotated at various level of abstraction (see Figure 12). For instance, *induction of apoptosis by hormones* is a type of *induction of apoptosis*, which in turn is a part of *apoptosis*. *Apoptosis* represents a higher level of abstraction, more general, whereas *induction of apoptosis by hormones* represents a lower level of abstraction, more specific. When annotating the genes with the GO terms, efforts are made to annotate the genes with the highest level of details possible, which corresponds to the lowest level of

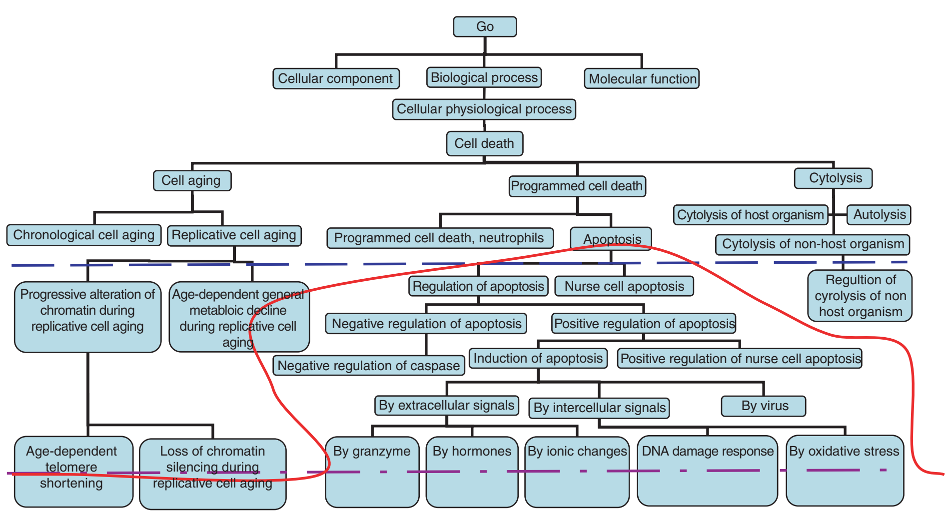

Figure 12 Levels of abstraction. The analysis can be performed at a lowest level of abstraction (purple dash-and-dot line), at a fixed level of abstraction chosen by the user (blue dashed line) or at a custom level of abstraction that can go to different depths in various subtrees of the GO (red continuous line)

abstraction. For example, if a gene is known to induce apoptosis in response to hormones, it will be annotated with the term *induction of apoptosis by hormones* and not merely with one of the higher level terms such as *induction of apoptosis* or *apoptosis*. A very valuable capability of a functional profiling tool is to let the user select a custom level of abstraction. From this point of view, the tools reviewed fall into one of the following three categories. The first category includes the tools able to perform the analysis only with the specific terms associated with each gene. This corresponds to an analysis undertaken at the lowest possible level of abstraction or the highest level of specificity (see the dash-and-dot line in Figure 12). This type of analysis is essentially a one-shot look-up into the annotation database used. Each data set can only be analyzed once since any further analysis can only provide the exact same results. The analysis cannot be directed to answer specific biological questions and cannot be refined in any way.

The second category of the tools include those tools that allow the user to select a predetermined depth, or level of abstraction in GO. Once this level is selected, these tools will consider any gene below the chosen level associated with the corresponding category at the chosen level. This is illustrated by the dashed line in Figure 12. The capability of choosing a predetermined depth allows the user to refine this analysis by performing it repeatedly, at various levels of abstraction, thus forcing various very specific terms to be grouped into more general, and perhaps more informative categories. It is often the case that each specific category does not appear to be significant because there are only few genes associated with it, while the more general category becomes highly significant once all the genes associated with specific subcategories are analyzed together as representing the more general category. Tools having this capability allow a more complex and detailed analysis that can be directed to ask specific biological questions.

Finally, the third category includes tools that allow a completely custom cut through the GO, at different levels of abstraction in different directions. If the analysis is performed at a fixed depth of 9 for instance, the analysis can distinguish between the various subtypes of apoptosis induction: by hormones, by extracellular signals, by intracellular signals, and so on (see Figure 12). However, for a fixed depth, the same analysis will also be performed on several other thousands of functional categories situated at the same level. If the results are presented in a bar graph, the interesting categories will be cluttered by all the extra categories that just happened to be at the same depth in GO, even though they may not be interesting to the researcher. At the same time, other phenomena may be missed because the chosen level may be too specific for those GO categories. A tool that allows a full customization is the most powerful since it will allow the user to perform the analysis at different depths in various parts of the GO hierarchy, as required by the specific biological hypothesis investigated. This is illustrated by the red continuous line in Figure 12.

Most of the existing tools only perform the analysis at the lowest level in GO, with the specific categories that genes have been annotated with, and do not allow any further refinement. Among the tools reviewed, FatiGO, EASEonline, and GOstat allow the user to select a specific level of abstraction before submitting the input list of genes. FatiGo and GOMiner also calculate a p-value for all nodes throughout the GO. This corresponds to a global static analysis in which all genes

under a certain node are considered to be associated with that node. Onto-Express is, at this time, the only tool that allows a fully customized analysis by allowing any node to be collapsed or expanded in the GO. Collapsing a node is equivalent to reassigning to this node all genes associated with any of its descendants. The p-value calculated for a collapsed node in Onto-Express corresponds to the p-value calculated in the global static analysis performed by GoMiner and FatiGo. Expanding a node will distinguish between genes associated with the node itself and the genes associated to any of it descendants. The p-value of an expanded node will be based only on the genes directly associated with it. This p-value is not provided by any other tool from those reviewed here. A current drawback in Onto-Express is that if a user wishes to perform the analysis at a fixed depth throughout GO, the user is required to manually expand the nodes up to this level.

4.7. Prerequisites and installation issues

Another important factor is the amount of effort necessary in order to install and use a tool. The Web-based services provide the experimental biologists a convenient solution by avoiding the problems usually associated with a local installation of a program (Zhang *et al*., 2004). On the other hand, tools available over the Web may be initially obstructed by security issues. For instance, if the tool uses a specific TCP/IP port and the researcher is behind a firewall, the required port must be open on the firewall before the tool can be used.

Stand-alone tools such as CLENCH, GoMiner, and GoSurfer force the user to understand the complexities of a software installation. For example, prerequisites for CLENCH include the prior installation of Perl modules for: (1) HTTP request handling, (2) file and console access, (3) common gateway interface (CGI), (4) database access, (5) statistical computation, and (6) graphical display (Shah, 2004). As another example, GoMiner requires the user to install the Adobe scalable vector graphics (SVG) and NCBI Cn3D browser plug-ins GoMiner. In comparison, the Web-based tools such as Onto-Express, EASEonline, DAVID, Ontology Traverser, GOTree Machine (GOTM), FuncAssociate, FatiGO only require that the user has a web browser with an Internet connection.

The most important problem in this category is the version control. From this point of view, the Web-based tools are far superior because the researcher can always be assured that they are using the very latest version of the software. The software or database updates are always done on the server, by the team who initially wrote the tool. For stand-alone tools, the burden of version control usually rests upon the user who is required to check periodically for new releases and updates. Once such an update becomes available, the burden of software or data update rests again with the user who has to go over the installation process again. In many cases, the updated version works worse than the older version due to issues related to the local environment. In principle, stand-alone tools can try to address this issue by providing automatic software updates. However, this approach means that the updating software must correctly identify, and appropriately deal with, various local software environment issues that tend to be slightly different over the potential hundreds or thousands of different installations.

4.8. Data sources

Most of the available tools use annotation data from a single public database. This has the advantage that the data is always as up-to-date as the database used. The disadvantage is that no single database offers a complete picture. The secondary analysis is more powerful if more types of data are integrated in a coherent way. A dedicated annotation database that integrates various types of data from various sources is potentially more useful than any single database. The drawback is that such a database is (1) difficult to design and (2) will need to be updated every time any one of its source databases is. This places a heavy burden on the shoulders of the team maintaining it. Given this, it is understandable that most tools use only one of the available annotation databases. EASEonline, GOSurfer, eGOn, and GOTM use LocusLink, whereas GeneMerge, GoMiner, and GOToolBox use the GO database. Onto-Express uses its own Onto-Tools database, which is currently the only attempt to integrate resources from several annotation databases. Currently, Onto-Tools uses data from, and it is linked to GenBank, dbEST, UniGene, LocusLink, RefSeq, Gene Ontology, and KEGG. Onto-Tools also uses data from NetAffx and Wormbase without being linked to them.

5. Conclusions

This paper discusses comparison of several ontological analysis tools implementing a very similar functional profiling approach. The comparison used the following criteria: statistical model(s) used, type of correction for multiple comparisons, reference microarrays available, scope of the analysis, visualization capabilities, capabilities for analysis at a custom level of abstraction, prerequisites and installation issues, and the sources of annotation data.

Short Specialist Review

Extracting networks from expression data

Vassily Hatzimanikatis and Eleftherios T. Papoutsakis
Northwestern University, Evanston, IL, USA

Development of sophisticated analytical technologies has enabled the cell-wide monitoring of gene and protein expression, and protein–protein and protein–DNA interactions (*see* Article 91, **Creating and hybridizing spotted DNA arrays**, Volume 4, Article 92, **Using oligonucleotide arrays**, Volume 4, Article 100, **Protein microarrays as an emerging tool for proteomics**, Volume 4, Article 103, **SAGE**, Volume 4, Article 1, **Core methodologies**, Volume 5, Article 20, **Separation-dependent approaches for protein expression profiling**, Volume 5, Article 21, **Separation-independent approaches for protein expression profiling**, Volume 5, Article 22, **Two-dimensional gel electrophoresis**, Volume 5, Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5, Article 24, **Protein arrays**, Volume 5, Article 28, **Real-time measurements of protein dynamics**, Volume 5, Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5, Article 30, **2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis**, Volume 5, Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5, Article 32, **Arraying proteins and antibodies**, Volume 5, Article 37, **Inferring gene function and biochemical networks from protein interactions**, Volume 5, Article 38, **The *C. elegans* interactome project**, Volume 5, Article 39, **The yeast interactome**, Volume 5, and Article 44, **Protein interaction databases**, Volume 5). These technologies allowed the study of the responses of the genetic and protein networks to environmental and genetic perturbations, and the identification of genes associated with diseased phenotypes. In the analysis of mRNA and protein expression data, genes or proteins are clustered with respect to their similarity in expression changes (compared to a control cellular condition or a "global" or "reference" set of transcripts) on the basis of the hypothesis that genes that serve similar cellular functions, or subject to the same regulatory actions, should display similar expression patterns. Various mathematical and computational techniques have been introduced for the clustering and analysis of expression profiles of genes (Quackenbush, 2001; *see also* Article 50, **Integrating statistical approaches in experimental design and data analysis**, Volume 7, Article 54, **Algorithms for gene expression analysis**, Volume 7, Article 57, **Low-level analysis of oligonucleotide expression arrays**, Volume 7, Article 63, **Relevance networks**, Volume 7).

However, these methods do not allow the construction of genetic or protein interaction networks either between individual genes or groups of genes (clusters). In order to infer possible regulatory architectures in a genetic or protein network, more sophisticated, model-based identification methods are required.

Model-based identification methods are based on the formulation of a mechanistic model of mRNA mass balances, that is, synthesis rate minus degradation rate. The synthesis of each mRNA is also considered to be under the regulation of multiple gene products. These models involve a set of structural parameters and a set of quantitative parameters. The structural parameters represent the number and identity of the genes that regulate the expression of each gene, and the type of regulation, for example, induction or repression. The quantitative parameters represent the strength of the regulatory interactions, the transcriptional efficiency of each gene, and the half-lives of the gene products. Once such a model has been formulated, mathematical and computational methods are employed for the identification of the structural and quantitative parameters. Estimation of the structural parameters will lead to the identification of the genetic regulatory network. Estimation of the associated quantitative parameters will allow the formulation of a mathematical model of the genetic network that could be used to predict network responses to environmental and genetic changes.

Several genetic network models have been proposed, which integrate biochemical-pathway information and expression data to trace genetic regulatory interactions (Akutsu *et al*., 2000; Dasika *et al*., 2004; Ideker *et al*., 2001; Lin *et al*., 2003; Maki *et al*., 2001; Moriyama *et al*., 1999; Noda *et al*., 1998; Thomas *et al*., 2004; Van Someren *et al*., 2000; Yeung *et al*., 2002; Gardner *et al*., 2003; *see also* Article 109, **Analyzing and reconstructing gene regulatory networks**, Volume 6, Article 110, **Reverse engineering gene regulatory networks**, Volume 6, and Article 118, **Data collection and analysis in systems biology**, Volume 6). They range from abstract Boolean descriptions to detailed mechanistic models and from Bayesian networks to neural network models (Bower and Bolouri, 2001; D'Haeseleer *et al*., 2000; Friedman *et al*., 2000). Every representation has its advantages and limitations with respect to its ability to infer structural and quantitative parameters in genetic networks.

One of the first approaches to infer the structural properties of a genetic network based on information of mRNA profiles employed a Boolean modeling framework (Somogyi *et al*., 1997). Boolean networks model the state of the gene as either ON or OFF and the input–output relationships are postulated as logical functions. Further improvements of the Boolean-based frameworks introduced Mutual Information (Liang *et al*., 1998) and an entropy-based approach (Ideker *et al*., 2000) in order to identify the experiments required for discrimination between alternate genetic networks predicted by these frameworks. Rigorous analysis has led to the identification of the number of experiments required for the identification of the Boolean model that is consistent with the data (Akutsu *et al*., 2000; Somogyi *et al*., 1997). However, in real systems, transcript levels vary in a continuous manner, implying that the key assumptions underlying Boolean network models may not be appropriate, and thus, more general models may be necessary.

Several continuous modeling frameworks have also been proposed, and they employ linear models (Chen *et al*., 1999; D'Haeseleer *et al*., 1999; Van Someren

et al., 2000; Weaver *et al*., 1999; Yeung *et al*., 2002; Gardner *et al*., 2003), hybrid Boolean and power law models (Akutsu *et al*., 2000), Bayesian models (Friedman *et al*., 2000), and linear models for inferring time delay in genetic networks (Dasika *et al*., 2004). Linear models cannot capture the inherent nonlinearities of biological systems. A possible approach then is to use the S-system, power-law framework whereby the nonlinearity of genetic regulation can be reasonably captured (Akutsu *et al*., 2000; Lin *et al*., 2003; Thomas *et al*., 2004).

The challenges in extracting networks from expression data arise from the type of data, the dimensionality of the data, the combinatorial nature of gene expression regulation, and the mathematical representation of the genetic network. Since every mathematical model is an approximation of the real biological system, methods for the identification of regulatory interactions should introduce the minimum number of simplifications and allow the identification of multiple possible regulatory interactions that are consistent with the experimental data. This would provide the expert with alternative hypothetical networks that could be evaluated on the basis of expert knowledge and literature information, while guiding experiments for hypothesis validation.

The data can be either temporal, that is, relative gene expression over time, or nontemporal, that is, relative expression over different time-invariant conditions. In most of the proposed methodologies, temporal data are discretized over time, and they are analyzed using frameworks similar to those developed for the analysis of nontemporal data. However, such discretization depends on the time interval of the sampling, and it might introduce biases that could lead to false estimation of the structural and quantitative parameters. Frequent sampling and improved identification methods tailored to the temporal nature of the data might help in improving network extraction from temporal expression data.

One of the biggest limitations in the inference of genetic networks is the use of mRNA expression data alone. While the real regulatory input is the protein product of a gene, most of the mathematical models and the associated inference methods ignore the presence of proteins and they treat mRNAs as the regulatory inputs of the mRNA expression. Ideally, protein expression data should be combined with mRNA expression data in the identification studies wherever this is feasible. However, the cost and sophistication of technologies that allow genome-wide monitoring of protein expression is limiting the availability of such information. Alternatively, it has been proposed that mathematical models could approximately describe the relation between mRNA and protein expression and thus account for lack of information about protein expression. Such approximations involve mechanistic modeling of protein expression for nontemporal data (Thomas *et al*., 2004) or using time-lag action of an mRNA (due to delay in protein synthesis) in temporal data (Chen *et al*., 1999; Dasika *et al*., 2004).

In addition, most of the DNA microarray experiments provide information about the relative expression patterns, whereas most of the models treat this information as absolute concentration information. This limitation can be resolved either by obtaining an estimate of the absolute mRNA concentration levels, or with mathematical representations that formulate the constraints imposed by the mRNA and protein mass balances as constraints on the relative expressions (Akutsu *et al*., 2000; Thomas *et al*., 2004).

A number of studies have also led to some very important conclusions regarding the dimensionality of the data. The number of experiments required for the unique identification of the correct regulatory structure depends both on the number of genes and the number of simultaneously perturbed biophysical parameters in each experiment. The number of the experiments times the number of the biophysical parameters perturbed in each experiment should be a portion of the number of the genes in the system in order to identify a small number of alternative regulatory structures that could explain the data. This result suggests that the required number of experiments could be decreased if in each experiment the number of the perturbed biophysical parameters is increased. Similar considerations suggest that identification of the regulatory structure based on single-gene knockout experiments might require the knockout of every gene (Thomas *et al*., 2004).

In addition, if there are two or more genes whose expression profiles across the different experiments are linearly dependent, any model-based identification method will fail to identify a unique regulatory structure consistent with the data. This could be the case for coregulated genes, or for genes that appear to be coregulated within the accuracy of the experimental methods. This finding led to the suggestion of clustering the coregulated genes into a single "gene" and studying the interactions of this new "gene" in the network (D'Haeseleer *et al*., 1999; Van Someren *et al*., 2000). The identified regulatory connections could then be due to interactions of single or multiple members of the cluster, and closer investigation of the elements in the cluster might help in refining the regulatory network.

Another element contributing to the complexity in reconstructing genetic regulatory networks is the combinatorial nature of regulation. The protein products of multiple genes can regulate the expression of a single gene and in multiple alternative output combinations. For a single gene with K regulatory input, $\left(2^2\right)^k$ regulatory functions are possible. Experimental methods such as chip-on-chip (chromatin immunoprecipitation on a chip (DNA array)) and sequence analysis computational methods would allow one to postulate possible regulatory interactions or to exclude genes from acting as regulators. Integration of this information into the identification frameworks will require the employment of computational frameworks that can enforce the presence or absence of regulatory interactions, as well as the maximum number of regulatory inputs per gene. Mixed-integer programming, the class of optimization methods that involves both discrete and continuous variables, offers the possibility of efficiently dealing with such constraints where the regulatory interaction of each gene with another gene is modeled using a binary variable with values 0 or 1 in the absence or presence, respectively, of this interaction (Dasika *et al*., 2004; Lin *et al*., 2003; Thomas *et al*., 2004). The Mixed-integer formulation can also allow the identification of multiple alternative regulatory networks that are consistent with the data. When such methods identify multiple structures, it is also observed that certain identified regulatory interactions are common in every alternative structure. This suggests that the regulatory interactions that are common in the identified alternative structures are highly probable to be present in the original system.

Finally, the accuracy of the mathematical models used in model-based inference methods plays an important role in the outcome of the analyses. While a detailed, nonlinear mechanistic model of transcription and translation will be able to capture

important aspects of the regulatory complexity, the accuracy of the data, the relatively small amount of experimental information, and the large size of the system do not allow meaningful computational analysis and network identification. Therefore, simpler models with a small number of quantitative parameters are necessary. A better understanding on the model reduction, from the full, nonlinear mechanistic models to simplified nonlinear or linear models is very important in developing model-based inference methods.

Future developments of frameworks for extracting networks from expression data need to address these challenges. The most powerful frameworks should be able to provide experimentalists with alternative hypotheses and molecular models that could be evaluated based on biological expertise and additional experimental studies.

Short Specialist Review

Data standardization and the HUPO proteomics standards initiative

Henning Hermjakob, Chris Taylor, Sandra Orchard, Weimin Zhu and Rolf Apweiler
European Bioinformatics Institute, Cambridge, UK

An increasing number of large-scale proteomics studies are currently being published or are in progress, providing a wealth of data and biological insights on a new scale. From protein expression and interactions to posttranslational modifications, data becomes available at an amazing rate. However, large-scale proteomics technologies are still far from the reliability levels of gene sequencing; comparative analyses are therefore essential to improve reliability (von Mering *et al*., 2002). The combination of different data types, for example, protein interactions and gene expression, allow new biological insights, but such integrative approaches are currently difficult and in many instances are impossible due to the fragmentary nature of proteomics data. Unlike other domains of molecular biology, for example, DNA (Kulikova *et al*., 2004; Galperin, 2004) and protein sequences (Apweiler *et al*., 2004), protein structures (Bourne *et al*., 2004) and gene expression (Brazma *et al*., 2003), no well-established databases exist, and the proteomics data supporting publications is often not available at all, or is scattered over supplementary tables and authors' and journals' websites in numerous formats. In addition to data collection, this also renders the scientific scrutiny of experimental conclusions based on the underlying data very time consuming if not impossible. The public availability of large microarray data sets has contributed to the improvement of statistical approaches and has led to important insights gained through the combination of published data with new data sets (Gygi *et al*., 1999); such approaches would usually be difficult in the proteomics domain as it currently stands.

The tide is turning though: an increasing awareness of the need to systematically annotate and archive proteomics data is illustrated by the publication of several proposed schemata and public databases for such data (Wilke *et al*., 2003; Carr *et al*., 2004; Prince *et al*., 2004; Xirasagar *et al*., 2004; Pedrioli *et al*., 2004). However, with the exception of the PEDRo schema (Taylor *et al*., 2003), these systems are developed by individual institutions or small groups of institutions and, as a result, suffer from problems with respect to community ownership and acceptance.

The HUPO Proteomics Standards Initiative (PSI) (Orchard *et al*., 2003) is constituted to define standards for data representation in proteomics, with which to

facilitate data comparison, exchange, and verification. PSI standards are developed in an open, community-based process, where participation of all interested parties is invited. The PSI initially focused on two priority areas for data integration; protein interactions and mass spectrometry. Additionally, the development of a representation of a complete proteomics experiment is ongoing; as is the generation of guidelines laying out the level of detail that is expected to adequately describe protocols, data, and analyses.

The HUPO PSI Molecular Interaction standard (MI) has been jointly developed by major interaction data providers from both the academic and commercial sectors, among them Hybrigenics (**http://www.hybrigenics.fr**), DIP (**http://dip.doe-mbi.ucla.edu/**), BIND (**http://bind.ca/**), MINT (**http://cbm.bio.uniroma2.it/mint/**), Cellzome (**http://www.cellzome.com/**), and IntAct (**http://www.ebi.ac.uk/intact/**). The PSI MI standard is developed in a layered approach, with successive levels providing increasing expressive power, obviously at the cost of increasing complexity. PSI MI 1.0 was published in February 2004 (Hermjakob *et al*., 2004), providing a basic exchange format for protein interaction data. PSI MI formatted data is provided by amongst others MINT, IntAct, HPRD (**http://www.hprd.org**), and DIP; a number of compatible tools are also available. Using PSI MI, it is now possible to connect data and tools from independent organizations, without any data conversion scripting, such as dynamically loading interaction data from IntAct into the Cytoscape analysis tool (**http://www.cytoscape.org**). A full list of PSI MI data and tool resources is in the documentation at **http://psidev.sourceforge.net/mi/xml/doc/user/**. PSI MI level 2, released in autumn 2004, adds additional interactor types, in particular, small molecules, DNA, and RNA. Using the PSI MI format, a number of major interaction data providers have established the International Molecular-Interaction Exchange (IMEx) consortium, through which they will regularly exchange user-submitted data; this is similar to the EMBL/GenBank/DDBJ collaboration, and will underpin synchronized, stable, reliable resources for molecular interaction data.

The PSI mass spectrometry work group (PSI MS) has developed the mzData format; a vendor-independent representation of mass spectra, providing a unified format for data archiving and exchange, and for search engine input. It has been jointly developed by academic users, commercial users, and instrument vendors; amongst them Eli Lilly, EBI, Bruker, Matrix Science, Shimadzu (Kratos), Applied Biosystems/MDS Sciex, Agilent, Waters (Micromass), and Thermo Electron. A controlled vocabulary, in particular, for instrument parameters, has been developed for use with mzData, which will be maintained jointly by the American Society for Mass Spectrometry (ASMS) and PSI; this controlled vocabulary builds on work by the American Society for Testing and Materials (**http://www.astm.com/**) on the Analytical Data Interchange standard (**http://andi.sourceforge.net/**).

The implementation phase for mzData is underway at the time of writing; all major mass spectrometer vendors, and other companies such as Matrix Science (peptide/protein identification software vendor), are scheduled to provide mzData import/export this year. In the next step, the mass spectrometry work group will provide mzIdent, a standard search engine output format designed to make peak list search results (i.e., peptide and/or protein identifications) comparable and amenable

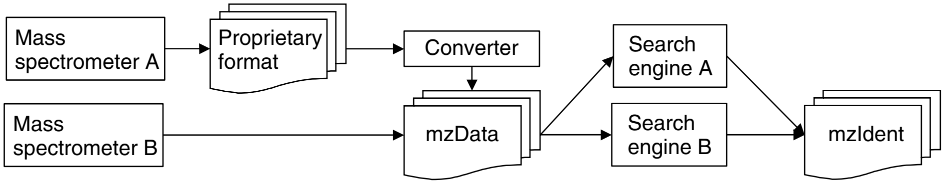

Figure 1 Proposed mass spectrometry data flow based around the formats developed by the PSI-MS workgroup: Mass spectrometers either directly generate mzData files or have their output formats converted to mzData, which itself then serves as a standard input format for search engines. The PSI's standard search engine output format (mzIdent) will then allow an easy comparison of search results from different search engines, and facilitate their postprocessing and submission to public repositories

to standardized postprocessing. Figure 1 shows the complete data flow for a mass-spec-based proteomics experiments.

In addition to PSI MI and MS, there exists a third HUPO PSI workgroup, Global Proteomics Standards (GPS); this workgroup concerns itself with the full description of proteomics experiments, comprising sample preparation, separation and analysis, and the collection and processing of results (a similar scope to that of the PEDRo schema; Taylor *et al*., 2003). The GPS workgroup's efforts fall into three broad areas: First, the Minimum Information About a Proteomics Experiment (MIAPE) guidelines – the analog of the Minimum Information About a Microarray Experiment (MIAME) guidelines for a microarray experiment (Brazma *et al*., 2001) – which lay out the minimum level of detail required for a description of a dataset, and the work that generated it, to a level considered sufficient to both understand and potentially recreate that work. Second, an object model (PSI-OM) and derived XML format (PSI-ML) with which to capture the data and metadata from any proteomics experiment (mzData, mzIdent, and the nascent GelML format for gel electrophoresis all represent components of this overall format). Lastly, the PSI ontology, which shares the same broad scope as the PSI-ML/OM; this ontology incorporates the controlled vocabulary developed for mass spectrometry data described above, and will itself ultimately be fully integrated into the MGED Ontology (**http://www.mged.org/ontology/**; Stoeckert and Parkinson, 2003).

As variously described above, all three PSI workgroups strive to standardize not only data formats but also contents, through the provision of guidelines, documentation, and in particular, through the development or adoption of controlled vocabularies and ontologies. As an example, there are more than 10 different spellings for the "yeast two-hybrid" technology (Legrain and Selig, 2000), for example, Y2H, 2H, two-hybrid; while equivalents are often straightforwardly interpretable by a human, such "families" of terms describing single key concepts make automated searches in large databases very difficult. Where possible, PSI uses existing reference systems, for example, GO (Harris *et al*., 2004) or the MGED ontology, while developing additional controlled vocabularies where necessary, for example, for PSI MI to describe specific methodologies to determine protein interactions. In addition, documentation, and guidelines documents such as MIAPE provide guidance in the use of the PSI formats. Such detailed usage instructions are essential to avoid the fragmentation of standards into dialects, where different data

sets are compliant to a standard, but are not compatible with each other, because flexibilities in the format are differently interpreted.

Beyond the recommendation of standards, the PSI aims to coordinate the implementation of public repositories accepting and providing data in PSI formats, and collaborates with scientific journals and funding agencies to encourage scientists to support their publications with underlying data sets made available through standardized, freely accessible public resources.

The PSI strongly encourages active participation in its work groups. For further information and mailing lists, please refer to the project's web pages at **http://psidev.sf.net/**.

Large error models for microarray intensities

Wolfgang Huber

1. Motivation

An error model is a description of the possible outcomes of a measurement. It depends on the true value of the underlying quantity that is measured and on the measurement apparatus. For microarrays, the quantities that one wants to measure are the abundances of specific molecules in a biological sample. The measurement apparatus consists of a cascade of biochemical reactions and an optical detection system with a laser scanner or a CCD camera. Biochemical reactions and detection are performed in parallel, allowing up to millions of measurements on one array.

What is the purpose of constructing error models for microarrays? There are three aspects:

1. An appreciation of the distribution of all possible outcomes of a measurement is necessary for basing *inference* on one or a limited number of measurements. Consider an experiment in which we want to compare gene expression in the colons of mice that were treated with a certain substance and mice that were not. If we have many measurements, we can simply compare their empirical distributions. For example, if the values from 10 replicate measurements for the *DMBT1* gene in the treated condition are all larger than 10 measurements from the untreated condition, the Wilcoxon test tells us that with a p-value of 10^{-5} the level of the transcript is really elevated in the treated mice. But often it is not possible, too expensive, or unethical, to obtain so many replicate measurements for all genes and for all conditions of interest. Often, it is also not necessary. If we are sufficiently confident in an error model, we are able to draw significant conclusions from fewer replicates.

2. An error model is an efficient tool for the summarization and *reporting* of experimental results. If we have reason to be confident that the measured

outcomes follow a certain distribution, then they are sufficiently described by that distribution's parameters, for example, mean and standard deviation; it may then not be necessary to report all of the individual measurements.

3. An error model is a summary of past experience and of our understanding of the measurement apparatus. It can be used for *quality control*: if the distribution of a new set of data greatly deviates from the model, this may direct our attention to quality issues with these data.

2. The additive-multiplicative error model

Consider the following generic observation equation

$$z = f(x, y) \tag{1}$$

where z is the outcome of the measurement, x is the true underlying quantity that we want to measure, the function f represents the measurement apparatus, and $y = (y_1, \dots, y_n)$ is a vector that contains all other parameters on which the functioning of the apparatus may depend. The functional dependence of f on some of the y_i may be known, on others it may not. Some of the y_i are controlled by the experimenter, some are not. If the measurement apparatus is well constructed, then f is a well-behaved, smooth function, and we can write equation (1) as

$$z = f(0, y) + f'(0, y)x + O(x^2) \tag{2}$$

where $f(0, y)$ is the baseline value that is measured if x is zero, f' is the derivative of f with respect to x, $f'(0, y)$ is a gain factor, and $O(x^2)$ represents nonlinear effects. By proper design of the experiment, the nonlinear terms can be made negligibly small within the relevant range of x. Examples for the parameters y in the case of microarrays are the efficiencies of mRNA extraction, reverse transcription, labeling and hybridization reactions, amount and quality of probe DNA on the array, unspecific hybridization, dye quantum yield, scanner gain, and background fluorescence of the array. All of these have an influence either on the baseline $f(0, y)$ or the gain $f'(0, y)$. Ideally, the parameters y could be fixed exactly at some value $\overline{y} = \left(\overline{y}_1, \dots, \overline{y}_n\right)$. In practice, they will fluctuate around $\overline{y}$ between repeated experiments. If the fluctuations are not too large, we can expand

$$f(0, y) \approx f(0, \overline{y}) + \sum_{i=1}^{n} \frac{\partial f(0, \overline{y}}{\partial y_i} (y_i - \overline{y}_i) \tag{3}$$

$$f'(0, y) \approx f'(0, \overline{y}) + \sum_{i=1}^{n} \frac{\partial f'(0, \overline{y})}{\partial y_i} (y_i - \overline{y}_i) \tag{4}$$

The sums on the right-hand sides of equations (3) and (4) are linear combinations of a large number n of random variables with mean zero. Thus, it is a reasonable approximation to model $f(0, y)$ and $f'(0, y)$ as normally distributed random

variables with means $a = f(0, \overline{y})$ and $b = f'(0, \overline{y})$ and variances σ_a^2 and σ_b^2, respectively.

Thus, omitting the nonlinear term, equation (2) leads to

$$z = a + \varepsilon + bx(1 + \eta) \tag{5}$$

with $\varepsilon \sim N(0, \sigma_a^2)$ and $\eta \sim N(0, \sigma_b^2/b^2)$. This is the *additive-multiplicative error model* for microarray data, which was proposed by Ideker *et al*., (2000). Rocke and Durbin, (2001) proposed it in the form

$$z = a + \varepsilon + bx\exp(\eta) \tag{6}$$

which is equivalent to equation (5) up to first order terms in η. Models (5) and (6) differ significantly only if the coefficient of variation σ_b/b is large. For microarray data, it is typically smaller than 0.2, thus the difference is of little practical relevance.

One of the main predictions of the error model (5) is the form of the dependence of the variance Var(z) of z on its mean E(z):

$$\mathrm{Var}(z) = v_0^2 + \frac{\sigma_b^2}{b^2}\,(\mathrm{E}(z) - z_0)^2 \tag{7}$$

that is, a strictly positive quadratic function. In the following, we will assume that the correlation between ε and η is negligible. Then the parameters of equation (7) are related to those of equation (5) via $v_0^2 = \sigma_a^2$ and $z_0 = a$. If the correlation is not negligible, the relationship is slightly more complicated, but the form of equation (7) remains the same.

3. Nesting

Consider a situation in which the quantity x from equation (6) is itself the result of a process whose outcome is approximately described by an additive-multiplicative error model,

$$x = a' + \varepsilon' + b'x'\exp(\eta') \tag{8}$$

The resulting distribution of z can again be described by an additive-multiplicative model with new parameters. This means that the class of models of the form (6) is closed under such hierarchical nesting, and the range of its applicability can be quite large.

For example, equation (6) could be used as a model for microarray measurements in a study of diseased tissues, with x the true abundance of a certain gene transcript in the tissue from an individual patient, while equation (8) could model the population distribution of this gene's transcript levels in a set of similar tissues from different patients.

4. Detection of differentially expressed genes

Suppose we want to compare two measurements z_1, z_2 that are distributed according to equation (6) with the same parameters a, b, σ_a, and σ_b, but possibly with different values of x_1, x_2. We want to find a function $h(z_1, z_2)$ that fulfills the two conditions:

$$\begin{array}{llcll} \text{(i) antisymmetry:} & h(z_1, z_2) & = & -h(z_2, z_1) & \forall x_1, x_2 \\ \text{(ii) homoskedasticity:} & \mathrm{Var}(h(z_1, z_2)) & = & \text{const} & \text{independent of } x_1, x_2 \end{array} \tag{9}$$

An approximate solution is given by Huber *et al*. (2003)

$$h(z_1, z_2) = \operatorname{arsinh}\left(\frac{z_1 - a}{\beta}\right) - \operatorname{arsinh}\left(\frac{z_2 - a}{\beta}\right) \tag{10}$$

with $\beta = \sigma_a b/\sigma_b$. If both z_1 and z_2 are large, this expression coincides with the log ratio

$$q(z_1, z_2) = \log(z_1 - a) - \log(z_2 - a) \tag{11}$$

However, $q(z_1, z_2)$ has a large, diverging variance for $z_i \to a$, a singularity at $z_i = a$, and is not defined in the range of real numbers for $z_i < a$. These unpleasant properties are important for applications: many genes are not expressed or only weakly expressed in some, but not all conditions of interest. That means, we need to compare conditions in which, for example, x_1 is large and x_2 is small. The log ratio (11) is not a useful quantity for this purpose, since the second term will wildly fluctuate and be sensitive to small errors in the estimation of the parameter a. In contrast, the statistic (10), which is called the *generalized log ratio* (Rocke and Durbin, 2003), is well defined everywhere and robust against small errors in a. It is always smaller in magnitude than the log ratio (see also Figure 1):

$$|h(z_1, z_2)| < |q(z_1, z_2)| \qquad \forall z_1, z_2. \tag{12}$$

The exponentiated value

$$\widehat{FC} = \exp(h(z_1, z_2)) \tag{13}$$

can be interpreted as a shrinkage estimator for the *fold change* x_1/x_2. It is more specific, that is, it leads to fewer false-positives in the detection of differentially expressed genes, than the naive estimator $(z_1 - a)/(z_2 - a)$ (Huber *et al*., 2002; Durbin *et al*., 2002).

5. Normalization and parameter estimation

The explanatory power of the model (6) can be greatly increased if we take into account the systematic dependence of its parameters on known experimental factors.

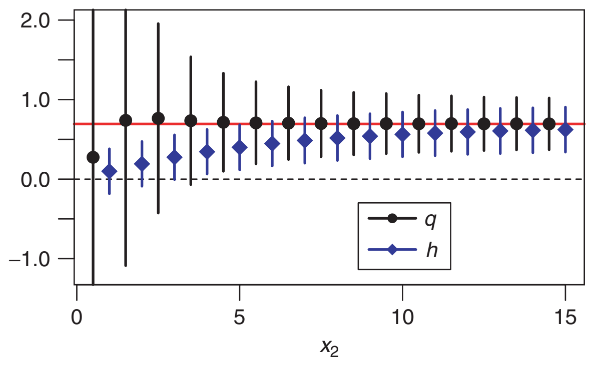

Figure 1 The shrinkage property of the generalized log ratio h. Blue diamonds and error bars correspond to mean and standard deviation of $h(z_1, z_2)$, cf. equation (10), black dots and error bars to $q(z_1, z_2)$, cf. equation (11). Data were generated according to equation (6) with $x_2 = 0.5, \ldots, 15$, $x_1 = 2x_2$, $a = 0$, $\sigma_a = 1$, $b = 1$, $\sigma_b = 0.1$. The horizontal line corresponds to the true log ratio $\log(2) \approx 0.693$. For intensities x_2 that are larger than about 10 times the additive noise level σ_a, h and q coincide. For smaller intensities, we can see a *variance-bias trade-off*: q has no bias but a huge variance, thus an estimate of the fold change based on a limited set of data can be arbitrarily off. In contrast, h keeps a constant variance – for the price of systematically underestimating the true fold change

This is often called *normalization*. A parametrization that captures the main factors that play a role in current experiments is

$$z_{ip} = a_{i,s(p)} + \varepsilon_{ip} + b_{i,s(p)} B_p x_{j(i),k(p)} \exp(\eta)_{ip} \tag{14}$$

Here, p indices the probes on the arrays and $k = k(p)$ the genes. Each probe is intended to represent exactly one gene, but one gene may be represented by several probes. B_p is the probe affinity of the pth probe (Li and Wong, 2001; Irizarry *et al*., 2003). i counts over the arrays and, if applicable, over the different dyes. $j = j(i)$ labels the biological conditions (e.g. normal/diseased). $a_{i,s(p)}$ and $b_{i,s(p)}$ are normalization offsets and scale factors that may be different for each i and possibly for different groups of probes $s = s(p)$. Probes may be grouped according to their physicochemical properties (Wu and Irizarry, 2004) or array manufacturing parameters such as print-tip (Dudoit *et al*., 2002) or spatial location. In the simplest case, $a_{i,s(p)} = a_i$ and $b_{i,s(p)} = b_i$ are the same for all probes on an array (Beißbarth *et al*., 2000). The noise terms ε and η are as above.

A method for the estimation of these parameters that uses the variance stabilizing transformation (10) was described by Huber *et al*. (2002) and Huber *et al*. (2003); software is available as an R package (Huber, 2004).

Relevance networks

Atul J. Butte
Children's Hospital, Boston, MA, USA

There are several ways one can classify the algorithms used in the analysis of large RNA expression data sets (Article 53, **Statistical methods for gene expression analysis**, Volume 7). One way is to make the distinction between supervised and unsupervised methods. Supervised methods typically involve finding predictors of conditions or labels, such that unknown cases can be accurately predicted or labeled. Supervised methods are typically trained and tested using real cases, so metrics such as sensitivity, specificity, and accuracy can be evaluated. Differing from this, unsupervised methods involve finding characteristics of a data set without a priori labels. These algorithms may find helpful or significant patterns within a dataset, like the commonly applied hierarchical clustering (Eisen *et al*., 1998), as opposed to finding an efficient way to predict a "correct answer". Algorithms that determine a network of associations between genes generally fall in the category of unsupervised methods, and the method of relevance networks falls within this group of algorithms. Other network determination algorithms used in the analysis of genomic measurements include Boolean networks (Liang *et al*., 1998; Wuensche, 1998; Szallasi and Liang, 1998) and Bayesian networks (Heckerman, 1996; Friedman *et al*., 2000; *see also* Article 60, **Extracting networks from expression data**, Volume 7).

Relevance networks offer a method for constructing networks of similarity, with the principal advantages being the ability to (1) include features of more than one data type, (2) represent multiple connections between features, and (3) capture negative as well as positive correlations. Like hierarchical clustering, the algorithm begins by evaluating the similarity of features by comprehensively comparing all features with each other in a pairwise manner over the same cases. Several dissimilarity measures have been used in this methodology, including mutual information (Butte and Kohane, 2000) and the correlation coefficient (Butte *et al*., 2000). Those pairwise associations that do not exceed a threshold measure are then ignored, and the remaining associations are visualized as a graph, with features as nodes and associations as edges.

Formally, relevance networks are defined and implemented as a graph where n nodes $(g_1, g_2, \ldots, g_n)$ are connected by p sets of m edges each holding a score, where $m = \frac{n^2-n}{2}$. Each of the p sets of edges completely connects the n nodes, and each pair of nodes is connected by a single edge with a score. In practice, p is typically one, as only a single dissimilarity measure is typically used at a time. Each of the p sets of edges can represent a different dissimilarity measure

(such as Euclidean distance, correlation coefficient, or mutual information), and several of these may be simultaneously applied to the same set of n nodes. When used with microarray data, genes are represented as nodes, and edges are labeled with a real-valued score, which represents the strength of association between two genes.

Relevance networks are viewed by specifying a subset of nodes and edges specified by the values $t_1 \ldots t_p$, considered as thresholds, and the functions $f_1 \ldots f_p$, applying each threshold to the appropriate set of the p sets of edges. Each of the p sets of edges has a threshold t and a function f for applying that threshold to each of the edges in that set. Only those edges where the function returns true are kept in the subset. Typically, if the set of edges contains values between -1.0 and 1.0, then t is set to a value between 0 and 1, and f returns true for every edge if the absolute value score of the edge is greater than t. The semantics of the edges when the algorithm is used with microarray data is that an edge with a higher-positive or lower-negative score is more likely to represent a hypothesis of a biological relationship. Using thresholds essentially breaks apart the completely connected network graph into sets of smaller subgraphs. Typically, the threshold values are determined by studying the false discovery rates of various potential thresholds from a repeated analysis of permuted data sets.

We will now discuss some advantages of using relevance networks. First, relevance networks naturally handle negative interactions. One example of an important negative interaction in biology is that of *p53,* a tumor suppressor gene that is known to suppress expression of other genes. In such an interaction, increased expression of *p53* could be associated with decreased expression levels of other genes. Negative interactions are clearly different than of no interaction. Hierarchical clustering, as commonly computed with correlation coefficients and Euclidean distances, miss negatively correlated interactions; simultaneously visualizing both positive and negative associations in the same tree is not defined. By ignoring negative associations, the behavior of tumor suppressor genes and other negative transcriptional factors could be missed.

Second, while hierarchical clustering effectively clusters data of a single data type, mixing alternate measurements with expression measurements is not defined. For example, clustering a data set with both phenotypic and expression measurements will result in trees in which the leaves of phenotypic measurements are scattered throughout the tree; it is not clear how this would be useful. Because of this, two-dimensional dendrograms are typically used to mix two data types, where phenotypic and expression measurements are separately clustered (Ross *et al*., 2000), but this adds to the complexity. Compared to this, relevance networks can naturally mix phenotypic measurements with expression measurements, and direct hypotheses and links are provided between different type data (Butte *et al*., 2000). This is important as more experiments are designed integrating data across multiple genome-scale modalities.

There are other minor advantages to using relevance networks. Features can only be positioned in a single place in hierarchical clustering. Each gene is directly connected to the tree with only one stem. In reality, a transcription factor may be responsible for regulating the expression of multiple other genes, but hierarchical clustering may directly link that transcription factor only with the one gene it

most closely resembles in expression pattern. With relevance networks, if a gene is closely linked to few or many other genes, then each link is shown separately. This is also important when a gene is similar to two different groups of genes, or when a pharmaceutical agent displays activity similar to two different classes of compounds (Butte *et al*., 2000).

Relevance networks have appeared in several publications. We initially applied the method to clinical laboratory results, as a proxy for patient phenotypic data, for unsupervised medical knowledge discovery without a prior model or information, and found networks that were easily validated with known relationships in physiology and pathophysiology, as well as novel links (Butte and Kohane, 1999). We then applied the method to gene expression measurements in yeast, using mutual information as a dissimilarity measure (Butte and Kohane, 2000). To find putative functional relationships between pairs of genes and pharmaceuticals, we applied relevance networks to a pharmacogenomic data set. Specifically, we joined a database of baseline RNA expression levels measured from the NCI60 human cancer cell line panel with a database of cell line susceptibility measures against a panel of anticancer agents, to see how baseline gene expression levels across the cell lines correlated with the growth inhibition of these same cell lines from thousands of anticancer agents. At the threshold used, we found only one network containing an association between a gene and an anticancer agent (Butte *et al*., 2000).

Relevance networks were used to study resistance to anticancer drugs and expression of various genes in human hepatoma cells (Moriyama *et al*., 2003). The methods were used to identify a network of coregulated genes in mice in which dysferlin was knocked out, as a model for limb girdle muscular dystrophy (Lennon *et al*., 2003). Relevance networks across a large collection of 60 human microarray data sets helped in elucidating functionally related gene associations (Lee *et al*., 2004).

A Java-based software package to compute and display relevance networks, called RelNet, is publicly available from the Children's Hospital Informatics Program at **http://www.chip.org/relnet**.

Introductory Review

Protein structure analysis and prediction

William R. Taylor
National Institute for Medical Research, London, UK

1. Introduction

Of all biological macromolecules, proteins exhibit the greatest diversity of structure and function. Virtually all the processes that we associate with life, both basic and esoteric, are carried out or enabled by proteins. It follows that the more we know and understand about proteins, the more we know about Life – not only how it functions but also how it goes wrong in diseases.

Over the past 40 years, our knowledge of protein structure has gradually accumulated, initially through the efforts of X-ray crystallographers and, over the past 20 years, joined by NMR spectroscopists. The number of known structures is now considerable (*see* Article 37, **Signal peptides and protein localization prediction**, Volume 7), and what is apparent is that protein structures often reveal in a very direct way how things work. On the whole, proteins do not function through some abstract diffuse effects but behave more like little machines that trap, chop, bind, and join the substrates on which they act – including sugars, nucleic acids, and lipids but principally each other.

Despite having very direct actions, given just a sequence or even structure, it is almost impossible to figure out from first principles what a protein will do. For example, if we know the structure of an enzyme (at high resolution), to determine what it does would be necessary to locate a binding pocket, analyze its shape to see what might fit, and then see if any catalytic groups fall in the correct juxtaposition (or could be moved into place) to effect the catalysis of some reaction. Like the ab initio folding problem (*see* Article 66, ***Ab initio* structure prediction**, Volume 7), this is an almost impossible task but, again like the structure prediction problem, if we have a collection of structures about which we have a lot of information, and if our mystery protein looks like one of them, we can make some pretty good guesses.

The extent to which we can rely on these "guesses" can be evaluated in two qualitatively different directions. In one, we hope to retain an overall match to the whole protein, and this dimension extends from the trivial case where the two sequences share 100% agreement (the same protein!), through clear but decreasing levels of similarity, to the region (sometimes called the "twilight zone") where the level of similarity has become so little that we can no longer be sure that we have a match between equivalent proteins. The methods based on this approach

fall into the area of homology modeling or, for the more difficult problems, fold recognition and threading (*see* Article 70, **Modeling by homology**, Volume 7). In the other direction, the overall fold of the protein is retained less firmly and instead fragments of similarity are used to suggest local structure. These fragments may come from one or many proteins and can range in size from a whole domain (where they meet homology modeling), through supersecondary structure and motifs down to the smallest fragments of single secondary structure and turns. At this limit, the result is just a secondary structure prediction, with no indication given of the fold of the protein (*see* Article 76, **Secondary structure prediction**, Volume 7).

Underpinning our ability to extrapolate information in this way from well-characterized proteins to novel proteins are comparison methods. Through the comparative analysis of known structures, we have built up some understanding of the degree to which sequence and structure are conserved between related proteins. Depending on the extent of similarity, these can use just sequence data, structural data, or both. Their application is limited by two fundamental, and still poorly characterized, conditions: first, how can we tell that a similarity is significant and not due to chance and, second, given a significant similarity, to what extent can the function and properties of one protein be transferred to the other.

2. Protein sequence and structure analysis

The comparison of protein structures began as soon as there was more than one known structure: specifically, the structures of myoglobin and hemoglobin. From this early point, it was immediately apparent that equivalent protein structures (having the same fold) can result from sequences that are very different. This emphasizes the power of comparing protein structures to see beyond similarities that are not obvious from just sequence data. (For details of the methods used in both these approaches, see Eidhammer *et al*., 2004).

2.1. Protein structure comparison

2.1.1. Residue-based comparison methods

Over the years, many methods have been developed to compare protein structures (*see* Article 75, **Protein structure comparison**, Volume 7). Most of these are based on the idea of optimal superposition of equivalent atoms or residues and the almost universal measure of how close the structures compare is the root-mean-square of the distance between equivalenced pairs (RMS or RMS deviation). This measure is not ideal under all circumstances, and variations have been developed that use the comparison of local subsets to avoid difficulties associated with the relative movement of substructures between the two proteins being compared.

Computational problems also arise in the initial determination of the equivalence between positions. This is an alignment problem, and the methods used in sequence comparison have been adapted to this more difficult domain. Despite the rigor of the RMS measure, the alignment of residues based on structure is not well

determined, and most methods adopt an iterative heuristic approach (*see* Article 75, **Protein structure comparison**, Volume 7). Because of this inherent uncertainty, although less than in sequence comparison, a structure-based alignment is not necessarily unique and a range of alternative alignments of comparable score must be considered.

2.1.2. Fold-based comparison methods

For the most distantly related protein structures, the methods outlined above may be too focused on the details to allow an overall similarity to be recognized in the fold (or part of the fold) of the two proteins. To concentrate on this "bigger picture", the details of the structures can be neglected, either by (literally) smoothing out the chain or by reducing secondary structure elements to simple line segments. Many structure comparison methods have been adapted to use this more reduced representation, which also has the advantage of comparing fewer points, typically an order of magnitude less, giving a corresponding increase in computation time.

When secondary structures are reduced to line segments (or "sticks"), an even greater reduction in the level of detail can be achieved by collapsing each stick to a point: turning the 3D protein representation into a 2D diagram. The resulting 2D representation is not always unambiguous, especially for larger and multidomain proteins, but for a typical domain size of 200–300 residues, the resulting figure is reasonably unique. These projections of structure are often "tidied up" either automatically or manually by placing secondary structure symbols on a regular lattice. The resulting figures are called "topology cartoons", and have proved useful from the earliest investigations of protein folds, especially for abstract concepts like handedness (see Taylor and Aszódi, 2005 for examples).

2.2. Sequence structure correlations

From the viewpoint of modeling and prediction, any correlations between structural features and the sequence are potentially useful. As outlined above, these extend from the overall fit of the sequence onto the structure down to fragments or motifs. As with all protein sequence analysis, the uncertainty of features used in the analysis can be reduced by using a multiple sequence alignment (Eidhammer *et al*., 2004).

Sequence/structure correlations can embody either generic properties such as hydrophobic amino acids with burial in the structure or more specific properties such as a particular configuration of residues that form a motif associated with a particular structure or function. The former tend to be approached using statistical methods, of which one of the most general is the Artificial Neural Net (ANN), while the latter are associated more with sequence alignment or pattern matching methods. Both approaches can, of course, be applied together to provide mutual support.

2.2.1. Secondary structure and exposure prediction

In situations where there is weak sequence similarity between the protein of unknown structure (target) and the protein of known structure (template), it is

possible to use the predicted secondary structure to support the match, both as an overall fit and for specific details of the alignment. The state of the art in secondary structure prediction and exposure is currently obtained through training an ANN on multiple sequence alignments, an approach used both in the PsiPred and PHD programs (*see* Article 76, **Secondary structure prediction**, Volume 7). The accuracy of these methods is around 80+%, however, it must be remembered that the spread of accuracy is wide and any individual prediction may be susceptible to considerable error, including variation in the predicted end points up to the total omission of some secondary structure elements.

Both secondary structure and exposure predictions can be used to constrain the alignment of sequences through the inhibition of gaps in secondary structure and their encouragement in regions with high predicted exposure. An improved alignment can, in turn, lead to a better prediction, and the process can be iterated.

Predicted residue states provide a powerful guide for matching a sequence directly onto a structure. In this type of match, commonly called "threading" (*see* Article 70, **Modeling by homology**, Volume 7), the predicted states can be aligned directly with the observed states in the known structure.

2.2.2. Motif matching

Progressing toward more remote similarity between sequences leads to the situation where the target sequence has no significant overall sequence similarity with any known structure but shares a fragmentary similarity (or motif) with a superfamily or class of protein. Such motifs typically indicate a wide group of proteins ranging in specificity from those that derive from a clearly related but diverse family (such as a protein kinase) to those that are associated with a particular function such as calcium binding (as in the EF-hand motif).

The problems associated with modeling a target sequence based on a motif are different to those utilizing an overall alignment. The regions outside the motif regions may be much more difficult to align or fit to any template, possibly because they indeed have a different structure. This may mean that the resulting model must also be left incomplete or predicted using ab initio methods (*see* Article 66, ***Ab initio* structure prediction**, Volume 7).

There are collections of motifs available on the Web, the oldest of which (PROSITE) has a comprehensive collection of patterns associated with most protein families. Other more specific collections can also be found, which have an association with a specific family or function (such as transcription factors) or protein modifications (such as signal sequences).

3. Protein structure prediction

The ideal of predicting the structure of a protein directly from just its amino acid sequence has long been held as the "Holy Grail" of theoretical calculations on proteins. Despite great increases in computation power over the last 30 years, this

goal seems almost as remote as ever. For small (20–30 residues), fast-folding proteins, the native structure can sometimes be calculated but this is far from the performance required to tackle the typical globular protein of biological interest.

Current approaches to this problem have strayed from the "true path" into a variety of hybrid methods that incorporate components of matching against known structures along the lines outlined above for sequence/structure comparison. Principal among these are fragment-based methods that attempt to assemble model structures from fragments drawn from the collection of known structures. These must be put together in a physically reasonable way and evaluated for their packing contribution. Similar approaches have attempted to "grow" model structures as a constrained (almost) random walk, again being evaluated for packing as parts are added (*see* Article 66, ***Ab initio* structure prediction**, Volume 7).

As evaluated by the CASP assessment (*see* Article 73, **CASP**, Volume 7), some of these methods have had good results on a limited number of proteins, which although small in size, are still much larger than anything that can be attempted by "pure" ab initio methods. This approach could be more widely applied if there was a good method to predict domains (or subdomains) of proteins, allowing a divide-and-conquer approach. Domain prediction from sequence is still, however, a very difficult problem (*see* Article 68, **Protein domains**, Volume 7), to the extent that one domain prediction methods even relies on an ab initio prediction method.

4. Future directions

The above survey summarizes the state of research on computational studies of protein sequence and structure, concentrating on methods that attempt to extract and correlate patterns from these data. As new data are gathered, often at an impressive rate, the balance between the power and use of the different methods will also change.

4.1. Structure and sequence genomics

As genomes are sequenced from many different organisms, we are now almost certain to have a few or several phylogenetically diverse sequences for the same protein from different organisms. This places greater importance on multiple sequence alignment methods and on any method that uses a multiple sequence alignment to derive properties. This includes many of the "threading" (or fold recognition) programs mentioned above and also the secondary structure prediction methods.

Similar data-gathering initiatives are also being pursued on the structural front in an attempt to find, if not every protein structure, at least a representative of each fold class. With such data, the ability to construct good molecular models of specific proteins within the family based on the nearest representative will be important. With increasing coverage of "fold space", the separation between target and template will decrease, placing greater emphasis on standard modeling tools

rather than on the more adventurous modeling based on distant or fragmentary similarity or even ab initio prediction.

4.2. Complexes with membranes and nucleic acid

The bulk of the structures being determined by the structural genomics initiatives are relatively small-to-medium sized globular proteins (that tend to crystallize more easily). This neglects both large partially unstructured multidomain proteins and also integral membrane proteins. While the large proteins might be solved as separate domains, there is still a problem of finding the best points where they can be broken into parts and also the problem of reconstructing a full overall structure of how the parts might function together (perhaps as part of an even larger protein complex). For this, electron microscopy and atomic force microscopy can provide the larger picture.

For membrane proteins, methods of structure determination are improving but there is a vast number of proteins that from their sequence can be clearly identified as membrane associated. This places increased importance on the computational analysis of membrane proteins (*see* Article 65, **Analysis and prediction of membrane protein structure**, Volume 7), and although there are good prediction methods for transmembrane helical segments, the prediction of three-dimensional structure is limited.

As computational work shifts toward larger assemblies, this will inevitably involve nucleic acid components both in the form of protein/RNA particles (including the ribosome) and in the interaction and control of genomic DNA. The latter has been widely studied from the viewpoint of protein/DNA binding interactions (*see* Article 77, **DNA/protein modeling**, Volume 7) and will undoubtedly progress toward larger assemblies such as chromatin and DNA packing.

5. Conclusions

When sufficient sequence data is available to form a link to a protein of known structure, then even if the similarity is weak, there is a good chance that a reasonable molecular model can be constructed. While such results may not be of sufficient accuracy to allow detailed binding analysis of substrates or drugs, they are often useful in rationalizing the effects of known mutations or identifying potential binding sites for other proteins.

In addition to these practical benefits, the comparison and modeling of different proteins also provide insight into how one structure might evolve into another. In extrapolating this evolutionary approach, it is possible to gain an idea of how the whole range of protein structures may have evolved from some basic architectures or Forms. The degree to which the protein structures that we see today are a product of their history or are constrained by "laws of structure" is not yet clear but with increasing numbers of known structures and ever more powerful computational tools for comparison and prediction, some answers may soon emerge.

Specialist Review

Analysis and prediction of membrane protein structure

Tina A. Eyre and Linda Partridge
University College London, London, UK

Janet M. Thornton
European Bioinformatics Institute, Cambridge, UK

1. Introduction

Transmembrane (TM) proteins are those that span the membrane lipid bilayer and they are estimated to comprise 20–50% of most genomes (Arkin *et al.*, 1997; Wallin and von Heijne, 1998). They are of great biological significance since they mediate most of the communication between cells and cellular compartments and contain many potential drug targets. Despite their abundance and importance, difficulties in the practical approaches to TM protein structure determination have led to few crystal structures being solved until recently. As a result, compared to water-soluble proteins, little is known about the structure of membrane proteins and, even today, only approximately 0.5% of the 23 792 structures in the Protein Data Bank (PDB Bernstein *et al.*, 1977) are TM proteins (Figure 1). An understanding of the structure of this class of protein is therefore desirable since it may facilitate structural modeling until high-throughput TM protein structure determination is possible.

As shown in Figure 2, the central region of the membrane consists of a highly hydrophobic 30-Å-thick lipid region formed by the hydrocarbon chains of the phospholipids. This is surrounded on either side by a 15-Å-thick region formed by the highly polar phospholipid head groups. The majority of TM proteins (known collectively as the α-bundle TM proteins) consist of several relatively hydrophobic α-helices, which span the membrane, connected by more polar loops. In contrast, the porin family of TM proteins, and possibly others, span the membrane via a barrel of β-strands and are not considered here. Proteins that span the membrane more than once are referred to as *polytopic*.

2. Characteristics of membrane protein structure

Since TM helices can now be readily identified from protein sequence (von Heijne and Gavel, 1988; Jayasinghe *et al.*, 2001; Jones *et al.*, 1994; Moller *et al.*, 2001),

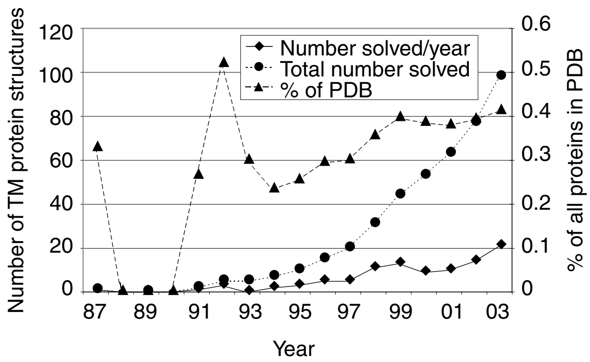

Figure 1 Plot showing the slow increase in the number of TM protein structures being solved each year and the proportion of the PDB made up by TM proteins. All structures are considered, including homologs

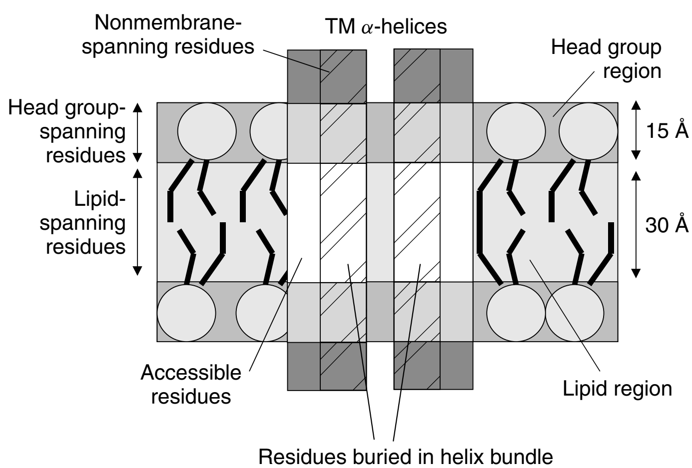

Figure 2 Schematic diagram showing the structure and thickness of a typical membrane and illustrating the different environments in which transmembrane residues may be found

the current challenge is to predict the 3D packing of these helices. Analysis of TM protein structures is therefore necessary to establish whether general rules can be identified to account for the folding of all membrane proteins and for use in model prediction. This is a particularly important goal, given the discrepancy between the number of TM proteins in the proteome and the number of structures known.

There are currently approximately 60 membrane protein structures known. Of these, only around 20 are nonhomologous polytopic α-helical proteins (Eyre *et al.*, 2004). Their structures are shown in Figure 3. This set is of interest since their multiple TM helices allow analysis of packing interactions, unbiased by inclusion of more than one member of each family. As a result, a number of characteristics of TM protein structure have been identified that are of particular relevance to

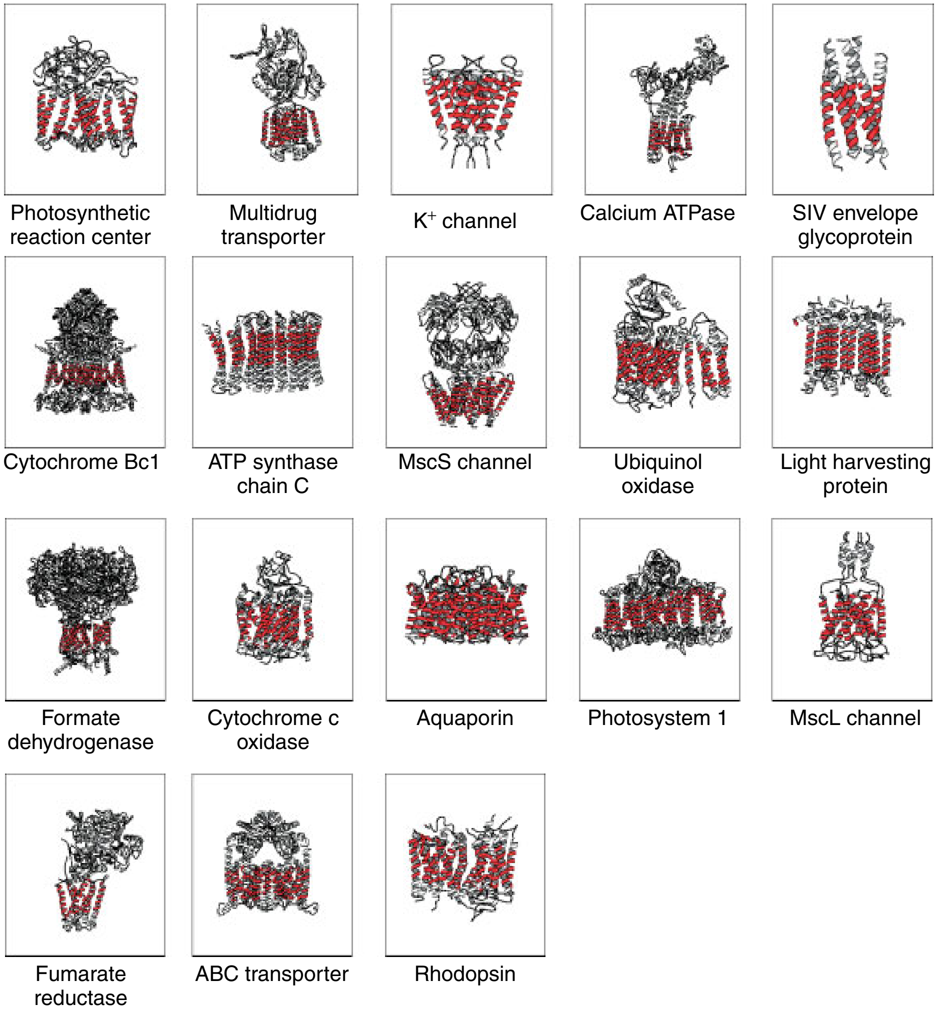

Figure 3 Currently available membrane protein structures showing the membrane lipid-spanning region in red

membrane protein modeling. These characteristics are described in the following sections.

3. Transmembrane helices are long, hydrophobic, and parallel

Figure 4 shows the preferences of each residue type for different regions of the membrane (Eyre *et al*., unpublished data). As would be expected from the hydrophobic nature of the bilayer, the lipid-spanning region of TM helices is enriched in hydrophobic amino acids compared to helices found in soluble proteins (Ulmschneider and Sansom, 2001) and to non-lipid-spanning regions of TM proteins (Eyre *et al*., 2004). This is the basis of many TM helix identification

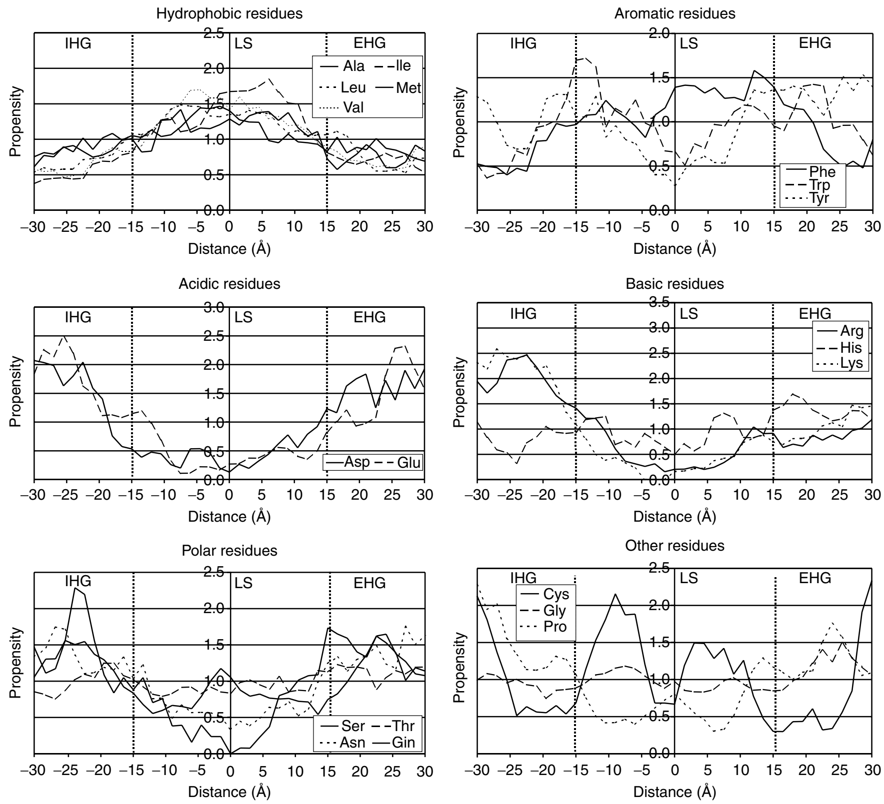

Figure 4 Plots showing the distribution of different residue types across the membrane-spanning region of 18 TM proteins. A propensity of greater than 1 indicates an enrichment in that area relative to other areas. IHG = intracellular head-group region, LS = lipid-spanning region, EHG = extracellular head-group region (Eyre *et al*., unpublished data)

algorithms. In addition, TM helices contain fewer charged and polar amino acids. Interestingly, however, the polar residues serine and threonine show no preference for either TM or non-TM regions. This is likely to be due to their ability to satisfy their hydrogen bonding requirements, even in the hydrophobic environment of the membrane lipid, by interaction with the previous backbone carbonyl oxygen of the same chain (Gray and Matthews, 1984). In addition, Figure 4 shows the 2.5-fold preference of the positively charged residues lysine and arginine for the intracellular head-group region, known as the *Positive Inside Rule*. This phenomenon is thought to be linked to the negative electrical potential that is found inside cells and may provide topological information during membrane insertion (von Heijne and Gavel, 1988).

Eyre *et al*. (2004) calculated various statistics concerning the number, length, and angle of α-helices and β-sheets in TM proteins and compared them to the corresponding values for soluble proteins. The results are broadly consistent with those obtained previously with smaller data sets (Bowie, 1997, Ulmschneider and Sansom, 2001). The average length of a TM helix is 23Å $\pm$ 4 residues (Eyre *et al*.,

2004). In contrast, the average length of both helices in soluble proteins and of non-TM helices in membrane proteins is only 9Å ± 5 residues (Eyre *et al*., 2004). The distributions of the lengths of non-TM α-helices and β-sheets between soluble and TM proteins are very similar. It can therefore be concluded that apart from the addition of several longer helices that span the membrane, TM proteins do not differ in their secondary structure composition from non-TM proteins.

The average angle of the helices to the membrane normal is $17 \pm 11^\circ$ (Eyre *et al*., 2004). This roughly parallel arrangement of TM helices is likely to facilitate the modeling of their packing in comparison to that for the helices in soluble proteins. However, there are large variations so that the degree of helix tilt cannot be ignored during modeling (Eyre *et al*., 2004).

Interestingly, while most TM helices are considerably longer than is required to span the membrane, the structures also contain a number of TM helices that only partially span the bilayer. The role of these helices remains unknown. Unfortunately, there appears to be no significant correlation between angle to the membrane normal and helix length (data not shown), excluding the possibility of estimating the tilt of a TM helix from its length during TM protein modeling.

4. There are differences between lipid-accessible and buried residues

The residues within the TM lipid-spanning regions of the helices can be considered to be found in one of the two main environments: either buried or accessible, as shown in Figure 2. The terms buried and accessible are used here to refer to the residues that are buried against other parts of the TM helix bundle or are exposed to membrane lipid, respectively, rather than the more common usage of buried or accessible relative to water. A small number of residues may also be found lining channels or cavities within the protein.

The different environments of lipid-exposed and buried residues result in different sequence characteristics. Specifically, lipid-accessible transmembrane helix residues are significantly more hydrophobic and less conserved than buried residues. In addition, lipid-accessible regions contain different residue types to buried regions (Eyre *et al*., 2004). It, therefore, is possible that membrane protein structure could be predicted by identifying the class to which different residues in the sequence are likely to belong. The characteristics of buried and lipid-accessible residues should be considered from this perspective.

Early analysis of the preferences of residues for buried or lipid-accessible positions was performed on the photosynthetic reaction center of *Rhodobacter sphaeroides* (Rees *et al*., 1989). Whereas in this TM protein the lipid-accessible residues were more hydrophobic than those buried (Rees *et al*., 1989), in soluble proteins, the buried residues were more hydrophobic (Chothia, 1976). Interestingly, the buried residues in the reaction center had a very similar hydrophobicity to residues buried within soluble proteins, as determined previously by Chothia (1976). Hence, soluble and TM proteins can be broadly considered to be internally stabilized in similar ways, with surface residues modified in order to facilitate solubility in the required medium. Certainly, TM proteins are not simply "inside-out"™

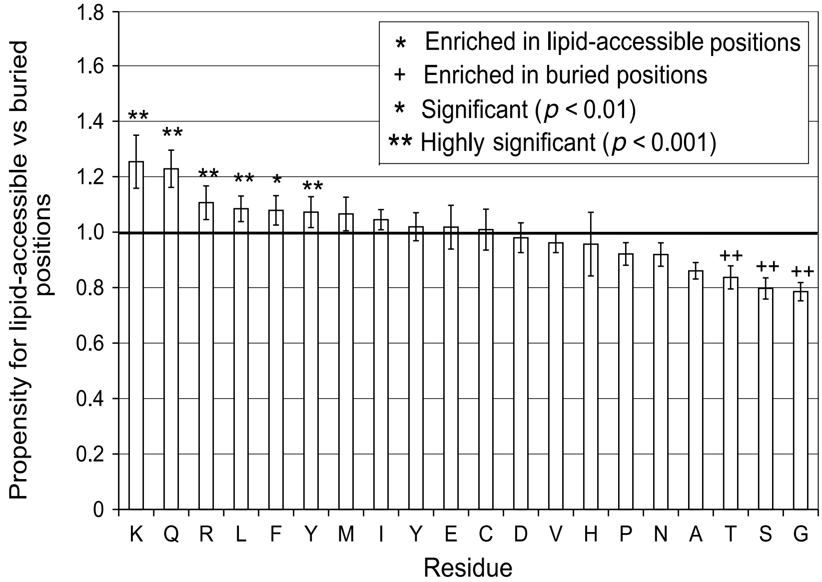

Figure 5 Residue preferences for lipid-accessible or buried positions in 18 TM proteins. Only residues in the lipid-spanning region are included. A value of greater than 50% indicates an enrichment in the lipid-accessible positions relative to buried positions. Similarly, a value of less than 50% indicates an enrichment in the buried positions relative to lipid-accessible positions. For details, see Eyre *et al*. (2004)

soluble proteins, with highly polar internal regions, as has been proposed (Stevens and Arkin, 1999). These results have been confirmed more recently using the 23 non-homologous TM protein structures that are now available (Eyre *et al*., 2004).

The work of Eyre *et al*. (2004) generally confirmed the results of the earlier smaller studies (Javadpour *et al*., 1999, Ulmschneider and Sansom, 2001). As shown in Figure 5, glycine, serine, and threonine are preferred in buried positions in TM proteins, whereas leucine, tryptophan, and phenylalanine prefer lipid-accessible positions. Hence, the general trend followed is that lipid-accessible residues tend to be more hydrophobic than those buried. Despite their hydrophilicity, the charged residues lysine and arginine, and the polar residue glutamine, strongly prefer lipid-accessible positions (Eyre *et al*., 2004). Possible explanations for this unexpected behavior are described below.

In addition to differences in residue content, lipid-accessible residues are significantly less conserved in terms of their sequence than buried residues are (Rees *et al*., 1989, Eyre *et al*., 2004). There is presumably strong selective pressure to conserve buried residues so that they continue to interact favorably with their interaction partners on other helices. There will be less selective pressure for lipid-exposed residues to be conserved since mutations in these residues are less likely to disrupt the folding, and hence the function, of the protein. As a result, throughout evolution, those individuals in which a protein contains mutations in a buried TM residue are likely to be less viable than those in which the protein contains mutations only in TM lipid-accessible residues. Hence, mutations in buried residues are less
